EIGHTH EDITION

JAMES D. CHERRY, MD, MSc

Distinguished Research Professor of Pediatrics
David Geffen School of Medicine at UCLA;
Attending Physician
Pediatric Infectious Diseases
Mattel Children's Hospital UCLA
Los Angeles, California

GAIL J. HARRISON, MD

Professor
Department of Pediatrics
Section of Infectious Diseases
Baylor College of Medicine;
Attending Physician
Infectious Diseases Service
Texas Children's Hospital
Houston, Texas

SHELDON L. KAPLAN, MD

Professor and Executive Vice-Chair
Head, Section of Infectious Diseases
Department of Pediatrics
Baylor College of Medicine;
Chief, Infectious Disease Service
Head, Department of Pediatric Medicine
Texas Children's Hospital
Houston, Texas

WILLIAM J. STEINBACH, MD

Professor of Pediatrics
Professor in Molecular Genetics and Microbiology
Chief, Pediatric Infectious Diseases
Director, Duke Pediatric Immunocompromised Host Program
Director, International Pediatric Fungal Network
Duke University School of Medicine
Durham, North Carolina

PETER J. HOTEZ, MD, PhD

Dean, National School of Tropical Medicine
Professor, Pediatrics and Molecular & Virology and
Microbiology
Head, Section of Pediatric Tropical Medicine
Baylor College of Medicine;
Endowed Chair of Tropical Pediatrics
Center for Vaccine Development
Texas Children's Hospital;
Professor, Department of Biology
Baylor University
Waco, Texas;
Baker Institute Fellow in Disease and Poverty
Rice University
Houston, Texas;
Co-Editor-in-Chief, *PLoS Neglected Tropical Diseases*

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Ralph D. Feigin, MD

April 3, 1938–August 14, 2008

This eighth edition of the *Textbook of Pediatric Infectious Diseases* is dedicated to Ralph D. Feigin. As everyone in pediatrics and, in particular, pediatric infectious diseases, knows, Ralph was an extraordinary individual, and his untimely death in 2008 leaves a void that will never be filled.

Ralph Feigin was born in New York City on April 3, 1938. He graduated from Columbia College in New York City in 1958 and received his M.D. from Boston University School of Medicine in 1962. He married Judith S. Zobel, a childhood friend, in 1960 while in medical school. Ralph completed his first two years of pediatric residency at Boston City Hospital and his third year at the Massachusetts General Hospital. He then fulfilled his military service requirement at the United States Army Research Institute of Infectious Diseases, Ft. Detrick, Frederick, Maryland. While at the United States Army Research Institute, he participated in significant studies relating to circadian periodicity and susceptibility to infections, as well as other studies that resulted in eight publications for which he was the first author. After completing his service commitment, he was Chief Resident at Massachusetts General Hospital during the 1967-68 academic year.

Ralph was recruited to Washington University in St. Louis by Phil Dodge in 1968, and soon thereafter he and one of us (JDC), who was then at St. Louis University, got together and forged an academic and personal friendship that continued until the time of his death. Over 40 years ago, Ralph and Jim recognized the need for a comprehensive book on pediatric infectious diseases, but because of their busy schedules the plan was put on hold, and in 1973 Jim moved to California. In 1976, the pediatric research meetings were held in St. Louis, and at this time Jim and Ralph met with W. B. Saunders representatives, and the book was conceived. The first edition of the textbook was published 5 years later in the fall of 1981. In comparison with this 8th edition, it was a modest effort, with 44 chapters and 124 contributors.

At Washington University and St. Louis Children's Hospital, Ralph developed one of the finest infectious diseases divisions in the country. His "Feigin Rounds" were an unparalleled learning experience and were legendary among medical students and residents. In 1977, Ralph moved to Houston, Texas, to accept the challenge of being the Chair of Pediatrics for Baylor College of Medicine and the Physician-in-Chief at Texas Children's Hospital. During the ensuing 30 years, the Department grew from 43 faculty members to almost 500. One of us (SLK) came under Ralph's spell in St. Louis and moved to Houston with him. Another one of us (GJH), an intern in Houston in 1977, was waiting for Dr. Feigin when he arrived.

In Houston, Ralph served as the Chair of Pediatrics for Baylor College of Medicine and the Physician-in-Chief at Texas Children's Hospital for 31 years. For 7 years of his tenure, he also served as President and CEO of Baylor College of Medicine. In addition to his commitments in Houston, Ralph served in leadership roles on more than 100 local, regional, and national committees and professional societies. His efforts in persuading government officials of all ranks helped children in Texas, the United States, and in all parts of the world. Many consider him to have been the foremost pediatrician in the world.

Not only was Dr. Feigin a powerhouse of energy, speed, and unsurpassed accomplishments, but he also was a gentleman, full of compassion, warmth, and kindness, and a man who kept people and patients first in his heart and mind. He was a loving husband to his wife, Judy, and a proud father to his three children, Susan, Debra, and Michael; doting grandfather to his six grandchildren, Rebecca, Matthew, Sarah, Rachel, Jacob, and Eli; and a mentor to so many in the field of pediatrics and pediatric infectious diseases. Ralph Feigin is missed by everyone who knew him, particularly by Judy Feigin and the family as well as by the present editors of this eighth edition of Feigin and Cherry.

James D. Cherry, MD, MSc
Distinguished Research Professor of
Pediatrics
David Geffen School of Medicine at UCLA;
Attending Physician
Pediatric Infectious Diseases
Mattel Children's Hospital UCLA
Los Angeles, California

Gail J. Harrison, MD
Professor
Department of Pediatrics
Section of Infectious Diseases
Baylor College of Medicine;
Attending Physician
Infectious Diseases Service
Texas Children's Hospital
Houston, Texas

William J. Steinbach, MD
Professor of Pediatrics
Professor in Molecular Genetics and Microbiology
Chief, Pediatric Infectious Diseases
Director, Duke Pediatric Immunocompromised Host Program
Director, International Pediatric Fungal Network
Duke University School of Medicine
Durham, North Carolina

Sheldon L. Kaplan, MD
Professor and Executive Vice-Chair
Head, Section of Infectious Diseases
Department of Pediatrics
Baylor College of Medicine;
Chief, Infectious Disease Service
Head, Department of Pediatric Medicine
Texas Children's Hospital
Houston, Texas

Peter J. Hotez, MD, PhD
Dean, National School of Tropical Medicine
Professor, Pediatrics and Molecular & Virology and Microbiology
Head, Section of Pediatric Tropical Medicine
Baylor College of Medicine;
Endowed Chair of Tropical Pediatrics
Center for Vaccine Development
Texas Children's Hospital;
Professor, Department of Biology
Baylor University
Waco, Texas;
Baker Institute Fellow in Disease and Poverty
Rice University
Houston, Texas;
Co-Editor-in-Chief, *PLoS Neglected Tropical Diseases*

W. Garrett Hunt, MD, MPH, DTM&H, FAAP

Associate Professor
Department of Pediatrics
Section of Infectious Diseases
Nationwide Children's Hospital/Ohio State University
Columbus, Ohio

W. Charles Huskins, MD, MSc

Professor of Pediatrics
Mayo Clinic School of Medicine;
Chair, Division of Pediatric Infectious Diseases
Mayo Clinic;
Vice Chair of Quality and Health Care Epidemiologist
Mayo Clinic Children's Center
Rochester, Minnesota

David Y. Hyun, MD

Senior Officer
Antibiotic Resistance Project
Pew Charitable Trusts
Philadelphia, Pennsylvania

Mary Anne Jackson, MD

Director, Infectious Diseases
Children's Mercy Kansas City
Professor of Pediatrics
UMKC School of Medicine
Kansas City, Missouri

Michael R. Jacobs, MB BCh, PhD

Professor of Pathology and Medicine
Department of Pathology
Case Western Reserve University;
Director of Clinical Microbiology
Department of Pathology
University Hospitals Cleveland Medical Center
Cleveland, Ohio

Richard F. Jacobs, MD, FAAP

Robert H. Fiser Jr, MD, Endowed Chair in Pediatrics
Pediatrician-in-Chief
Department of Pediatrics
Arkansas Children's Hospital;
Chairman and Professor
Department of Pediatrics
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Ravi Jhaveri, MD

Associate Professor
Department of Pediatrics
University of North Carolina at Chapel Hill School of Medicine
Chapel Hill, North Carolina

Audrey R. Odom John, MD, PhD

Associate Professor
Departments of Pediatrics and Molecular Microbiology
Washington University School of Medicine
Saint Louis, Missouri

Samantha H. Johnston, MD, MPH

Associate Physician
Pediatric Infectious Diseases
UCSF Benioff Children's Hospital Oakland
Oakland, California

Meena R. Julapalli, MD

Assistant Professor
Department of Dermatology
University of Colorado
Denver, Colorado

Sheldon L. Kaplan, MD

Professor and Executive Vice-Chair
Head, Section of Infectious Diseases
Department of Pediatrics
Baylor College of Medicine;
Chief, Infectious Disease Service
Head, Department of Pediatric Medicine
Texas Children's Hospital
Houston, Texas

Gregory L. Kearns, PharmD, PhD

President
Arkansas Children's Research Institute
Senior Vice President and Chief Research Officer
Arkansas Children's;
Ross and Mary Whipple Family Distinguished Research Scientist
Professor of Pediatrics
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Jessica M. Khouri, MD

Senior Medical Officer
Infant Botulism Treatment and Prevention Program
California Department of Public Health
Richmond, California

Kwang Sik Kim, MD

Professor and Director
Department of Pediatric Infectious Diseases
Johns Hopkins University School of Medicine;
Professor
Department of Molecular Microbiology and Immunology
Johns Hopkins University Bloomberg School of Public Health
Baltimore, Maryland

Yae-Jean Kim, MD, PhD

Associate Professor
Department of Pediatrics
Samsung Medical Center
Sungkyunkwan University School of Medicine
Seoul, Korea

Katherine Y. King, MD, PhD

Assistant Professor
Department of Pediatric Infectious Diseases
Baylor College of Medicine
Houston, Texas

Louis V. Kirchhoff, MD, MPH

Professor
Department of Internal Medicine (Infectious Diseases), Psychiatry,
and Epidemiology
Carver College of Medicine and College of Public Health
University of Iowa
Iowa City, Iowa

Martin B. Kleiman, MD

Ryan White Professor Emeritus of Pediatrics
Ryan White Center for Pediatric Infectious Disease and Global
Health
Indiana University School of Medicine
Indianapolis, Indiana

Bruce S. Klein, MD

Gerard B. Odell and Shirley S. Matchette Professor of Pediatrics
Professor of Internal Medicine and Medical Microbiology and
Immunology
University of Wisconsin–Madison
Madison, Wisconsin

Stephan A. Kohlhoff, MD

Associate Professor
Departments of Pediatrics and Medicine
State University of New York Downstate Medical Center
New York, New York

Tobias R. Kollmann, MD, PhD

Professor of Pediatrics
Interim Head, Division of Infectious Diseases
University of British Columbia
Vancouver, BC, Canada

Poonum S. Korpe, MD

Assistant Scientist
Department of Epidemiology
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland

Margaret Kosek, MD

Assistant Professor
Department of International Health
Johns Hopkins University Bloomberg School of Public Health
Baltimore, Maryland

Michael P. Koster, MD

Division of Pediatric Hospital Medicine
Hasbro Children's Hospital;
Associate Professor, Clinical Educator
Department of Pediatrics
Alpert Medical School of Brown University
Providence, Rhode Island

Peter J. Krause, MD

Senior Research Scientist
Yale School of Public Health
Yale School of Medicine
New Haven, Connecticut

Leonard R. Krilov, MD

Chairman, Department of Pediatrics
Chief, Pediatric Infectious Disease
Children's Medical Center
NYU Winthrop Hospital
Mineola, New York;
Professor of Pediatrics
State University of New York Stony Brook School of Medicine
Stony Brook, New York

Paul Krogstad, MD

Professor
Departments of Pediatrics and Molecular and Medical Pharmacology
David Geffen School of Medicine at UCLA
Los Angeles, California

Damian J. Krysan, MD, PHD

Associate Professor
Departments of Pediatrics and Microbiology/Immunology
University of Rochester School of Medicine and Dentistry
Rochester, New York

Edward Kuan, MD, MBA

Resident Physician
Department of Head and Neck Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

Thomas Kuhls, MD

Department of Pediatrics
Norman Pediatric Associates
Norman, Oklahoma

Sarah M. Labuda, MD, MPH

Pediatric Infectious Diseases Fellow
Tulane School of Medicine
New Orleans, Louisiana

Paul M. Lantos, MD

Assistant Professor
Division of Pediatric Infectious Diseases
Division of General Internal Medicine
Duke University School of Medicine
Duke Global Health Institute
Durham, North Carolina

Timothy R. La Pine, MD

Professor
Department of Pediatrics and Pathology
University of Utah;
Director of Neonatology
St. Mark's Hospital
Salt Lake City, Utah

Suvi Heinimäki, PhD

Project Researcher
Vaccine Research Center
University of Tampere
Tampere, Finland

Jerome M. Larkin, MD

Division of Infectious Diseases
Rhode Island Hospital
Associate Professor, Clinical Educator
Department of Medicine
Alpert Medical School of Brown University
Providence, Rhode Island

Matthew B. Laurens, MD, MPH

Associate Professor
Institute for Global Health
University of Maryland School of Medicine
Baltimore, Maryland

Charles T. Leach, MD

Professor and Chief of Infectious Diseases
Department of Pediatrics
Baylor College of Medicine/Children's Hospital of San Antonio
San Antonio, Texas

Amy Leber, PhD

Director, Clinical Microbiology and Immunoserology
Department of Pathology and Laboratory Medicine
Nationwide Children's Hospital
Columbus, Ohio

Robert J. Leggiadro, MD

Adjunct Professor
Departments of Biology and Geography and the Environment
Villanova University
Villanova, Pennsylvania;
Adjunct Clinical Professor
Department of Pediatrics
Donald and Barbara Zucker School of Medicine at Hofstra/
Northwell
Hempstead, New York;
Adjunct Attending Physician
General Pediatrics
Cohen Children's Medical Center
New Hyde Park, New York

Deborah Lehman, MD

Professor
Department of Pediatrics
David Geffen School of Medicine at UCLA
Los Angeles, California

Diana R. Lennon, MB CHB, FRACP

Professor of Population Health, Child, and Youth
Department of Pediatrics
University of Auckland;
Pediatrician in Infectious Diseases
Department of Pediatrics
Starship and KidzFirst Children's Hospital
Auckland, New Zealand

Daniel H. Leung, MD

Associate Professor of Pediatrics
Division of Gastroenterology, Hepatology, and Nutrition
Baylor College of Medicine;
Director of Clinical Research
Medical Director, Viral Hepatitis Program
Texas Children's Hospital
Houston, Texas

Moise L. Levy, MD

Chief, Pediatric/Adolescent Dermatology
Dell Children's Medical Center;
Professor of Pediatrics and Medicine (Dermatology)
Dell Medical School
University of Texas
Austin, Texas;
Clinical Professor of Dermatology and Pediatrics
Baylor College of Medicine
Houston, Texas

W. Matthew Linam, MD, MS

Medical Director of Infection Prevention and Hospital Epidemiology
Associate Professor, Department of Pediatrics
Division of Pediatric Infectious Diseases
Arkansas Children's Hospital
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Latania K. Logan, MD

Chief, Pediatric Infectious Diseases
Department of Pediatrics
Rush University Medical Center
Associate Professor
Rush Medical College
Chicago, Illinois

Timothy E. Lotze, MD

Associate Professor of Pediatrics and Neurology
Division of Child Neurology
Baylor College of Medicine and Texas Children's Hospital
Houston, Texas

Yalda C. Lucero, MD, PhD

Pediatric Gastroenterologist
Assistant Professor
Microbiology and Mycology Program
Institute of Biomedical Sciences
Faculty of Medicine
University of Chile and Northern Campus Department of Pediatrics
Santiago, Chile

Debra J. Lugo, MD

Fellow, Pediatric Infectious Diseases
Mattel Children's Hospital
University of California—Los Angeles
Los Angeles, California

Berkley Luk, BSc

PhD Candidate
Program in Integrative Molecular and Biomedical Sciences
Baylor College of Medicine;
Department of Pathology
Texas Children's Hospital
Houston, Texas

Susan A. Maloney, MD, MHSc

Global Tuberculosis Coordinator
Division of Global Migration and Quarantine
National Center for Infectious Diseases
Centers for Disease Control and Prevention
Atlanta, Georgia

Michelle C. Mann, MD

Assistant Professor
Department of Pediatrics
Baylor College of Medicine
Houston, Texas

Lucila Marquez, MD, MPH

Assistant Professor of Pediatrics, Section of Infectious Diseases
Associate Medical Director, Infection Control and Prevention
Baylor College of Medicine and Texas Children's Hospital
Houston, Texas

Kimberly C. Martin, DO, MPH

Assistant Professor of Pediatrics
Division of Pediatric Infectious Diseases
University of Oklahoma School of Community Medicine
Tulsa, Oklahoma

Laurene Mascola, MD, MPH, FAAP

Epidemiology Consultant
Acute Communicable Disease Program
Los Angeles County Department of Public Health
Los Angeles, California

Edward O. Mason Jr, PhD

Professor
Department of Pediatrics
Baylor College of Medicine
Houston, Texas

Aldo Maspons, MD

CEO/Cofounder
VeMiDoc, LLC;
Maspons Pediatric Gastro
Pediatric Gastroenterology
El Paso, Texas

Marc A. Mazade, MD

Consultant
Pediatric Infectious Disease
Cook Children's Medical Center
Fort Worth, Texas

Holly E. McBride, MPH, MHS, PA-C

Physician Assistant
Internal Medicine
University of Colorado Health
Loveland, Colorado

Jonathan A. McCullers, MD

Chair
Department of Pediatrics
University of Tennessee Health Science Center
Memphis, Tennessee

Kenneth McIntosh, MD

Professor
Department of Pediatrics
Harvard Medical School;
Senior Physician
Department of Medicine
Children's Hospital
Boston, Massachusetts

James E. McJunkin, MD

Professor of Pediatrics
Department of Pediatrics
West Virginia University Health Sciences Center
Charleston, West Virginia

Kelly T. McKee Jr, MD, MPH

Vice President
Department of Public Health and Government Services
QuintilesIMS
Durham, North Carolina

Ross McKinney Jr, MD

Professor Emeritus
Department of Pediatrics
Duke University School of Medicine
Durham, North Carolina;
Chief Scientific Officer
Association of American Medical Colleges
Washington, DC

J. Chase McNeil, MD

Assistant Professor
Department of Pediatrics
Section of Infectious Diseases
Baylor College of Medicine
Houston, Texas

Rojelio Mejia, MD

Assistant Professor of Infectious Diseases and Pediatrics
National School of Tropical Medicine
Baylor College of Medicine
Houston, Texas

Asuncion Mejias, MD, PhD

Associate Professor of Pediatrics
Ohio State University College of Medicine
Department of Pediatrics
Division of Infectious Diseases
Nationwide Children's Hospital
Columbus, Ohio

Maria José Soares Mendes Giannini, PhD

Full Professor
Department of Clinical Analysis
Laboratory of Clinical Mycology
São Paulo State University-UNESP
Araraquara, São Paulo, Brazil

Marian G. Michaels, MD, MPH

Professor
Department of Pediatrics and Surgery
University of Pittsburgh School of Medicine
Division of Pediatric Infectious Diseases
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Ian C. Michelow, MD, DTM&H

Division of Pediatric Infectious Diseases
Hasbro Children's Hospital
Associate Professor
Department of Pediatrics
Alpert Medical School of Brown University
Providence, Rhode Island

Marjorie J. Miller, DrPH

Senior Specialist, Virology
Department of Pathology and Laboratory Medicine
UCLA Medical Center
Los Angeles, California

James N. Mills, PhD

Adjunct Faculty
Population Biology, Ecology, and Evolution Group
Emory University
Atlanta, Georgia

Leena B. Mithal, MD, MSCI

Attending Physician
Department of Pediatric Infectious Diseases
Ann & Robert H. Lurie Children's Hospital of Chicago;
Instructor, Department of Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Kathryn S. Moffett, MD

Professor of Pediatrics
Section Chief, Infectious Diseases
Department of Pediatrics
West Virginia University
Morgantown, West Virginia

Martin Montes, MD

Assistant Professor
Instituto de Medicina Tropica "Alexander von Humboldt"
Universidad Peruana Cayetano Heredia
Lima, Peru;
Assistant Professor
Department of Medicine
Division of Infectious Diseases
University of Texas Medical Branch
Galveston, Texas

Martha Muller, MD

Associate Professor
Department of Pediatrics
University of New Mexico
Albuquerque, New Mexico

Randy George Mungwira, MBBS, MPH

Blantyre Malaria Project
Blantyre, Malawi

James R. Murphy, PhD

Professor
Department of Pediatrics
University of Texas
Houston, Texas

Santhosh M. Nadipuram, MD

Postdoctoral Fellow
Department of Microbiology, Immunology, & Molecular Genetics
University of California—Los Angeles
Los Angeles, California

James P. Nataro, MD, PhD, MBA

Benjamin Armistead Shepherd Professor and Chair
Department of Pediatrics
University of Virginia School of Medicine;
Physician-in-Chief
University of Virginia Children's Hospital
Charlottesville, Virginia

Heather Needham, MD, MPH

Assistant Professor of Pediatrics
Section of Adolescent Medicine & Sports Medicine
Baylor College of Medicine and Texas Children's Hospital
Houston, Texas

Karin Nielsen-Saines, MD, MPH

Professor of Clinical Pediatrics
Division of Pediatric Infectious Diseases
David Geffen School of Medicine at UCLA;
Director, Center for Brazilian Studies
Los Angeles, California

Delma J. Nieves, MD

Assistant Clinical Professor
Department of Pediatric Infectious Diseases
University of California—Irvine School of Medicine
Children's Hospital of Orange County
Orange, California

Richard Oberhelman, MD

Professor and Chair
Global Community Health & Behavioral Sciences
Tulane School of Public Health and Tropical Medicine;
Professor of Pediatrics
Tulane School of Medicine
New Orleans, Louisiana

Theresa J. Ochoa, MD

Associate Professor
 Department of Pediatrics
 Instituto de Medicina Tropical "Alexander von Humboldt"
 Universidad Peruana Cayetano Heredia
 Lima, Peru;
 Associate Professor
 Division of Epidemiology, Human Genetics, and Environmental
 Sciences
 Center for Infectious Diseases
 School of Public Health
 University of Texas Health Science Center at Houston
 Houston, Texas

Rosemary M. Olivero, MD

Clinical Associate Professor of Pediatrics and Human Development
 Michigan State College of Human Medicine;
 Attending Physician
 Section of Pediatric Infectious Diseases
 Helen DeVos Children's Hospital
 Grand Rapids, Michigan

Miguel O'Ryan, MD

Professor, Pediatric Infectious Disease
 Millennium Institute of Immunology and Immunotherapy
 Faculty of Medicine
 Microbiology and Mycology Program
 Institute of Biomedical Sciences
 University of Chile
 Santiago, Chile

Gary D. Overturf, MD

Professor Emeritus
 Departments of Pediatrics and Pathology
 University of New Mexico School of Medicine;
 Medical Director, Infectious Diseases
 TriCore Reference Laboratories
 Albuquerque, New Mexico

Debra L. Palazzi, MD, MEd

Associate Professor of Pediatrics
 Section of Infectious Diseases
 Baylor College of Medicine;
 Chief, Infectious Diseases Clinic
 Texas Children's Hospital
 Houston, Texas

Pia S. Pannaraj, MD, MPH

Associate Professor
 Pediatrics and Molecular Microbiology and Immunology
 University of Southern California/Children's Hospital Los Angeles
 Los Angeles, California

Janak A. Patel, MD

Professor and Division Director
 Department of Pediatrics
 Division of Pediatric Infectious Disease and Immunology
 University of Texas Medical Branch
 Galveston, Texas

Mary E. Paul, MD

Associate Professor
 Department of Pediatrics
 Baylor College of Medicine
 Chief, Retrovirology and Global Health
 Texas Children's Hospital
 Houston, Texas

Stephen I. Pelton, MD

Professor of Pediatrics and Epidemiology
 Department of Pediatrics
 Boston University Schools of Medicine and Public Health;
 Chief, Section of Pediatric Infectious Diseases
 Department of Pediatrics
 Boston Medical Center
 Boston, Massachusetts

Morgan A. Pence, PhD, D(ABMM)

Clinical Microbiologist
 Department of Laboratory and Pathology
 Cook Children's Medical Center
 Fort Worth, Texas

John R. Perfect, MD

James B. Duke Professor of Medicine
 Duke University Medical Center
 Durham, North Carolina

C.J. Peters, MD

Department of Microbiology and Immunology
 University of Texas Medical Branch
 Galveston, Texas

William A. Petri Jr, MD, PhD

Chief
 Division of Infectious Disease and International Health
 University of Virginia Health System;
 Wade Hampton Frost Professor of Epidemiology
 University of Virginia
 Charlottesville, Virginia

Yen H. Pham, MD

Assistant Professor
 Department of Pediatric Gastroenterology, Hepatology, and
 Nutrition
 Baylor College of Medicine and Texas Children's Hospital
 Houston, Texas

Francisco P. Pinheiro, MD

Department of Arbovirus
 Instituto Evandro Chagas
 FNS
 Ministry of Health
 Belem, Brazil

Benjamin A. Pinsky, MD, PhD

Associate Professor
 Departments of Pathology and Medicine (Infectious Diseases)
 Stanford University School of Medicine;
 Medical Director
 Clinical Virology Laboratory
 Stanford Health Care and Stanford Children's Health
 Stanford, California

Alice Pong, MD

Department of Pediatric Infectious Diseases
 University of California–San Diego;
 Department of Pediatric Infectious Diseases
 Rady Children's Hospital San Diego
 San Diego, California

Eric A. Porsch, PhD

Department of Pediatrics
 Children's Hospital of Philadelphia
 Philadelphia, Pennsylvania

Joan S. Purcell, MD

Adolescent Medicine and Pediatrics
STEP Pediatrics
Woodlands, Texas

Natalie M. Quanquin, MD, PhD

Research Fellow
Department of Microbiology, Immunology, and Molecular Genetics
University of California–Los Angeles
Los Angeles, California

Kevin K. Quinn, MD

Physician
Department of Pediatric Infectious Diseases
Southern California Permanente Medical Group
Fontana, California

Susan M. Abdel-Rahman, PharmD

Chief, Section of Therapeutic Innovation
Clinical Pharmacology, Medical Toxicology & Therapeutic Innovation
Children's Mercy–Kansas City;
Professor of Pediatrics
University of Missouri–Kansas City School of Medicine
Kansas City, Missouri

Octavio Ramilo, MD

Henry G. Cramblett Chair in Medicine
Professor of Pediatrics
Ohio State University College of Medicine
Department of Pediatrics
Chief, Division of Infectious Diseases
Nationwide Children's Hospital
Columbus, Ohio

Ramya Ramraj, MD, MBBS

Affiliate Assistant Professor
Oregon Health and Sciences University;
Attending Pediatrician and Pediatric Gastroenterologist
Doernbecher Children's Hospital and Kaiser NW Permanente
Portland, Oregon

Paula A. Revell, PhD

Assistant Professor
Departments of Pathology and Immunology and Pediatrics
Baylor College of Medicine;
Director of Microbiology and Virology
Texas Children's Hospital
Houston, Texas

Anne W. Rimoin, PhD, MPH

Associate Professor
Department of Epidemiology
UCLA Fielding School of Public Health
Los Angeles, California

José R. Romero, MD

Horace C. Cabe Professor of Infectious Diseases
Department of Pediatrics
University of Arkansas for Medical Sciences;
Director, Pediatric Infectious Diseases Section
Department of Pediatrics
Arkansas Children's Hospital;
Director, Clinical Trials Research
Arkansas Children's Hospital Research Institute
Little Rock, Arkansas

Lawrence Ross, MD, DTM&H

Professor Emeritus
Division of Pediatric Infectious Diseases
Children's Hospital of Los Angeles
Keck School of Medicine at the University of Southern California
Los Angeles, California

Anne H. Rowley, MD

Professor
Department of Pediatrics and Microbiology/Immunology
Northwestern University Feinberg School of Medicine
Attending Physician, Division of Infectious Diseases
Department of Pediatrics
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

Charles E. Rupprecht, VMD, MS, PhD

Chief Executive Officer
LYSSA, LLC
Atlanta, Georgia

Xavier Saez-Llorens, MD

Professor of Pediatrics
Head of Infectious Diseases
Hospital del Niño “Dr. José Renán Esquivel”
Distinguished Investigator, SNI, Senacyt
Panama City, Panama

Julia Shaklee Sammons, MD, MSCE

Assistant Professor of Clinical Pediatrics
Division of Infectious Diseases
Perelman School of Medicine at the University of Pennsylvania;
Medical Director and Hospital Epidemiologist
Infection Prevention and Control
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Pablo Sánchez, MD

Principal Investigator
Center for Perinatal Research
Fellow, Infectious Diseases
Fellow, Neonatology
Nationwide Children's Hospital
Columbus, Ohio

Linette Sande, MD

Assistant Professor of Pediatrics
Department of Pediatric Infectious Diseases
Loma Linda University;
Attending Physician
Department of Pediatric Infectious Diseases
Loma Linda University Children's Hospital
Loma Linda, California

Javier Santisteban-Ponce, MD

Attending Physician
Pediatric Infectious Disease Unit
Department of Pediatrics
Hospital Nacional Edgardo Rebagliati Martins-EsSalud;
Lima, Peru

Laura A. Sass, MD

Assistant Professor
Department of Pediatrics
Eastern Virginia Medical School;
Attending Physician
Department of Pediatric Infectious Diseases
Medical Director, Infection Prevention and Control, Antibiotic Stewardship
Children's Hospital of The King's Daughters
Norfolk, Virginia

Stephen J. Scholand, MD

Associate Professor
Department of Medicine
Frank Netter School of Medicine
Quinnipiac University
North Haven, Connecticut

Danica J. Schulte, MD

Assistant Professor in Residence
Department of Pediatrics
University of California–Los Angeles;
Assistant Professor
Departments of Pediatrics, Pediatric Infectious Diseases,
Immunology and Allergy
Cedars-Sinai Medical Center
Los Angeles, California

Jennifer E. Schuster, MD, MSCI

Assistant Professor
Department of Pediatrics
Children's Mercy Kansas City
Kansas City, Missouri

Gordon E. Schutze, MD, FAAP

Professor of Pediatrics
Executive Vice Chairman
Martin I. Lorin, MD, Endowed Chair in Medical Education
Department of Pediatrics
Baylor College of Medicine;
Vice President, International Programs
Baylor International Pediatric AIDS Initiative at Texas Children's
Hospital
Houston, Texas

Patrick C. Seed, MD, PhD

Assistant Professor
Department of Pediatrics/Pediatric Infectious Diseases
Duke University School of Medicine;
Assistant Professor
Department of Molecular Genetics and Microbiology
Duke University School of Medicine
Durham, North Carolina

Jose A. Serpa, MD, MS

Associate Professor
Department of Medicine
Baylor College of Medicine
Houston, Texas

Samir S. Shah, MD, MSCE

Professor
Department of Pediatrics
University of Cincinnati College of Medicine;
Director, Division of Hospital Medicine
Attending Physician
Divisions of Infectious Diseases and Hospital Medicine
James M. Ewell Endowed Chair
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Eugene D. Shapiro, MD

Professor
Departments of Pediatrics, Epidemiology of Microbial Diseases, and
Investigative Medicine
Yale University
New Haven, Connecticut

Nina L. Shapiro, MD

Professor, Department of Head and Neck Surgery
Director, Division of Pediatric Otolaryngology
David Geffen School of Medicine at UCLA
Los Angeles, California

William T. Shearer, MD, PhD

Professor of Pediatrics and Pathology and Immunology
Distinguished Service Professor
Baylor College of Medicine;
Allergy and Immunology Service
Texas Children's Hospital
Houston, Texas

Robyn Shimizu-Cohen, CLS(ASCP)

Specialist
Department of Pathology and Laboratory Medicine
University of California–Los Angeles
Los Angeles, California

Stanford T. Shulman, MD

Chief Emeritus, Division of Infectious Diseases
Ann & Robert H. Lurie Children's Hospital of Chicago
Virginia H. Rogers Professor of Pediatric Infectious Diseases
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Kareem W. Shehab, MD

Assistant Professor
Department of Pediatrics
Section of Infectious Disease
University of Arizona
Tucson, Arizona

Ziad M. Shehab, MD

Professor of Pediatrics and Pathology
University of Arizona
Tucson, Arizona

Constantine Simos, DMD

Attending Surgeon
Oral and Maxillofacial Surgery
Robert Wood Johnson University Hospital
Saint Peter's University Hospital
New Brunswick, New Jersey;
Assistant Clinical Professor
Oral and Maxillofacial Surgery
Columbia University College of Dental Medicine
New York, New York

Michael A. Smit, MD, MSPH

Division of Pediatric Infectious Diseases
Hasbro Children's Hospital
Assistant Professor
Department of Pediatrics
Alpert Medical School of Brown University
Providence, Rhode Island

P. Brian Smith, MD, MPH, MHS

Professor of Pediatrics
Duke University Medical Center
Duke Clinical Research Institute
Durham, North Carolina

Priya R. Soni, MD

Fellow, Pediatric Infectious Disease
Mattel Children's Hospital
University of California–Los Angeles
Los Angeles, California

Sunil K. Sood, MBBS, DCH, MD

Professor
 Departments of Pediatrics and Family Medicine
 Hofstra Northwell School of Medicine
 Hempstead, New York;
 Chair of Pediatrics
 Southside Hospital, Northwell Health
 Bay Shore, New York;
 Attending Physician
 Pediatric Infectious Diseases
 Cohen Children's Medical Center
 New Hyde Park, New York

Mary Allen Staat, MD, MPH

Professor
 Department of Pediatrics
 University of Cincinnati College of Medicine;
 Director
 International Adoption Center
 Cincinnati Children's Hospital Medical Center
 Cincinnati, Ohio

Damien Stark, MSc, PhD, FASM, FACTM

Associate, Department of Medical and Molecular Biosciences
 University of Technology Sydney
 Broadway, NSW, Australia;
 Senior Hospital Scientist
 Department of Microbiology
 St. Vincent's Hospital
 Darlinghurst, NSW, Australia

Jeffrey R. Starke, MD

Professor
 Department of Pediatrics
 Baylor College of Medicine
 Houston, Texas

Victoria A. Statler, MD, MSc

Assistant Professor
 Department of Pediatric Infectious Diseases
 University of Louisville
 Louisville, Kentucky

Barbara W. Stechenberg, MD

Pediatric Infectious Diseases Specialist
 Department of Pediatrics
 Baystate Children's Hospital
 Springfield, Massachusetts;
 Professor Emerita of Pediatrics
 Department of Pediatrics
 Tufts University School of Medicine
 Boston, Massachusetts

William J. Steinbach, MD

Professor of Pediatrics
 Professor in Molecular Genetics and Microbiology
 Chief, Pediatric Infectious Diseases
 Director, Duke Pediatric Immunocompromised Host Program
 Director, International Pediatric Fungal Network
 Duke University School of Medicine
 Durham, North Carolina

Joseph W. St. Geme III, MD

Professor of Pediatrics and Microbiology
 Chair, Department of Pediatrics
 Perelman School of Medicine at the University of Pennsylvania;
 Chair, Department of Pediatrics
 Physician-in-Chief
 Children's Hospital of Philadelphia
 Philadelphia, Pennsylvania

Jeffrey Suen, MD

Private Practice
 Bakersfield, California

Lillian Sung, MD, PhD

Professor
 Division of Haematology/Oncology
 Hospital for Sick Children
 Toronto, ON, Canada

Douglas S. Swanson, MD

Associate Professor of Pediatrics
 Department of Pediatric Infectious Diseases
 Children's Mercy Kansas City;
 Associate Professor of Pediatrics
 University of Missouri–Kansas City
 Kansas City, Missouri

Tina Q. Tan, MD

Professor
 Department of Pediatrics
 Feinberg School of Medicine
 Northwestern University;
 Infectious Diseases Attending Physician
 Department of Pediatrics
 Ann & Robert H. Lurie Children's Hospital
 Chicago, Illinois

Ruston S. Taylor, PharmD

Department of Pharmacy
 Legacy Community Health
 Houston, Texas

Michael A. Tolle, MD, MPH

Assistant Professor
 Department of Pediatrics
 Retrovirology and Global Health Section
 International Pediatrics AIDS Initiative (BIPAI)
 Baylor College of Medicine Children's Foundation
 Texas Children's Hospital
 Houston, Texas;
 Tanzania Buganda Medical Centre
 Mwanza, Tanzania

Philip Toltzis, MD

Professor
 Department of Pediatrics
 Rainbow Babies and Children's Hospital
 Cleveland, Ohio

Stuart R. Tomko, MD

Division of Child Neurology
 Texas Children's Hospital
 Houston, Texas

Michael F. Tosi, MD

Professor of Pediatrics
 Division of Pediatric Infectious Diseases
 Mount Sinai School of Medicine
 New York, New York

Leidy J. Tovar Padua, MD

Fellow
 Division of Pediatric Infectious Diseases
 Mattel Children's Hospital of UCLA
 Los Angeles, California

Amelia P.A. Travassos da Rosa, BSc

Research Associate
Center for Tropical Diseases
Department of Pathology
University of Texas Medical Branch
Galveston, Texas

Theodore F. Tsai, MD, MPH

Senior Vice President, Scientific Affairs
Novartis Vaccines
Cambridge, Massachusetts

Andrew M. Vahabzadeh-Hagh, MD

Resident
Department of Head and Neck Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

Jorge J. Velarde, MD, PhD

Instructor
Division of Infectious Diseases
Boston Children's Hospital
Boston, Massachusetts

Jesus G. Vallejo, MD

Associate Professor
Department of Pediatric Infectious Diseases
Baylor College of Medicine
Houston, Texas

John A. Vanchiere, MD, PhD

Professor and Chief
Section of Pediatric Infectious Diseases
Louisiana State University Health Sciences Center
Shreveport, Louisiana

Robert S. Venick, MD

Associate Professor
Departments of Pediatrics and Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

Sanjay Verma, MBBS, MD

Additional Professor of Pediatrics
Advanced Pediatrics Centre
Postgraduate Institute of Medical Education and Research
Chandigarh, India

James Versalovic, MD, PhD

Pathologist-in-Chief
Department of Pathology
Texas Children's Hospital;
Milton J. Finegold Professor
Department of Pathology and Immunology
Baylor College of Medicine
Houston, Texas

Timo Vesikari, MD, PhD

Director
Vaccine Research Center
University of Tampere
Tampere, Finland

Ellen R. Wald, MD

Chair, Department of Pediatrics
University of Wisconsin School of Medicine & Public Health;
Pediatrician-in-Chief
American Family Children's Hospital
Madison, Wisconsin

Thomas J. Walsh, MD

Director, Transplantation-Oncology Infectious Diseases Program
Weill Cornell Medical Center of Cornell University
New York, New York

Mark A. Ward, MD

Associate Professor
Department of Pediatrics
Baylor College of Medicine
Houston, Texas

Rachel L. Wattier, MD, MHS

Assistant Clinical Professor
Department of Pediatrics
University of California—San Francisco
San Francisco, California

Sing Sing Way, MD, PhD

Professor of Pediatrics
Pauline and Lawson Reed Chair
Division of Infectious Diseases
Cincinnati Children's Hospital
University of Cincinnati College of Medicine
Cincinnati, Ohio

Jill Weatherhead, MD

Assistant Professor of Infectious Diseases and Pediatrics
National School of Tropical Medicine
Baylor College of Medicine
Houston, Texas

Michelle Weinberg, MD, MPH

Medical Epidemiologist
Immigrant, Refugee, and Migrant Health Branch
Division of Global Migration and Quarantine
Centers for Disease Control and Prevention
Atlanta, Georgia

Nicholas Weinberg, MD

Assistant Professor
Department of Emergency Medicine
Geisel School of Medicine
Dartmouth-Hitchcock Medical Center
Hanover, New Hampshire

Melanie Wellington, MD, PhD

Associate Professor
Department of Pediatrics
University of Rochester Medical Center
Rochester, New York

Robert C. Welliver Sr, MD

Professor of Pediatrics
Division of Pediatric Infectious Diseases
University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma;
Emeritus Professor of Pediatrics
Division of Pediatric Infectious Diseases
SUNY at Buffalo and Children's Hospital
Buffalo, New York

J. Gary Wheeler, MD, MPS

Professor of Pediatrics
Division of Infectious Diseases
University of Arkansas for Medical Sciences
Little Rock, Arkansas

A. Clinton White Jr, MD

Professor, Division of Infectious Disease
Department of Internal Medicine
University of Texas Medical Branch
Galveston, Texas

Suzanne Whitworth, MD

Medical Director
Department of Pediatric Infectious Diseases
Cook Children's Healthcare System
Fort Worth, Texas

Bernhard L. Wiedermann, MD, MA

Professor
Department of Pediatrics
George Washington University School of Medicine and Health
Sciences;
Attending Physician
Division of Infectious Diseases
Children's National Health System
Washington, DC

John V. Williams, MD

Professor and Chief
Pediatric Infectious Diseases
Henry L. Hillman Chair in Pediatric Immunology
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Natalie M. Williams-Bouyer, PhD, D(ABMM)

Associate Professor, Department of Pathology
Associate Director, Division of Clinical Microbiology
University of Texas Medical Branch;
Clinical Consultant, Clinical Laboratory Services
Shriners Hospitals for Children
Galveston, Texas

Charles R. Woods Jr, MD, MS

Professor and Vice Chair for Faculty Development
Department of Pediatrics
University of Louisville School of Medicine
Louisville, Kentucky

Terry W. Wright, PhD

Associate Professor
Department of Pediatrics
University of Rochester Medical Center
Rochester, New York

Nave Yeganeh, MD, MPH

Assistant Professor
Department of Pediatrics
Division of Pediatric Infectious Diseases
David Geffen School of Medicine at UCLA
Los Angeles, California

Edward J. Young, MD

Professor of Medicine
Baylor College of Medicine
Houston, Texas

Ramia Zakhour, MD

Clinical Instructor
Department of Pediatrics and Adolescent Medicine
Division of Pediatric Infectious Diseases

Associate Chief
Division of Infectious Diseases
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Morbidity and mortality rates related to infectious diseases decreased dramatically during the first half of the 20th century in the developed world because of major improvements in public health (e.g., clean water, adequate sanitation, and vector control) and personal health. Further major reductions occurred in the second half of that century following the introduction of antimicrobial therapy, as well as active and passive immunization efforts. Despite these advances, infectious diseases in the developed world remain the leading cause of morbidity in infants and children in the 21st century. Children in the United States continue to experience three to nine respiratory infections and one to three gastrointestinal illnesses annually, requiring visits to physicians that outnumber the visits made for the purpose of well-child care. Infectious diseases are also the most common cause of school absenteeism.

Children in low and middle income countries also experience high rates of respiratory and gastrointestinal infections, which are often more severe and more frequent than those in children in the developed world. In addition, in the developing world there are great morbidity and mortality due to parasitic and vector-borne diseases. Also of importance are “spillover” infectious diseases such as Ebola, which because of increased urbanization resulted in an extensive epidemic in three African countries in 2014–15. In addition, mosquito-borne diseases such as Zika and Chikungunya have increased in prevalence in the Americas.

In more recent years, the emergence of resistance to multiple antibiotics by a large number of bacterial microorganisms (e.g., community-associated methicillin-resistant *Staphylococcus aureus*) has contributed to this infection-related morbidity and mortality, as have new infectious agents (e.g., SARS and MERS coronaviruses) and changes in the clinical manifestations and severity of established infectious agents (e.g., enterovirus 71, swine influenza).

The first edition of *Textbook of Pediatric Infectious Diseases* was written because Drs. Feigin and Cherry and many of their colleagues were concerned that no single reference text existed that comprehensively covered infectious diseases in children and adolescents. With each subsequent edition, including this one, the goal has been to provide comprehensive coverage of all subjects pertinent to the study of infectious diseases in children. Any attempt to summarize our present understanding of infectious diseases for serious students of the subject is a formidable task. In many areas, new information continues to accrue so rapidly that material becomes dated before it can appear in a text of this magnitude. Nevertheless, in this edition the editors and their author colleagues have endeavored to provide the most comprehensive and up-to-date discussion of pediatric infectious diseases ever compiled. This new edition is available online as well as in print. Purchasers can access the online version by registering their personal identification number (PIN) (found on the inside front cover of the book) at expertconsult.inkling.com. Online access includes not only fully searchable text, photos, illustrations, and tables, but also references linked to PubMed.

To provide a text as comprehensive and authoritative as possible, we, the editors, have enlisted contributions from a large number of individuals whose collective expertise is responsible for whatever success we may have had in meeting our objective. We offer our most profound appreciation to the 307 fellow contributors from nearly 100 universities or institutions in 18 countries for their professional expertise and devoted scholarship. Their cooperation and willingness to work with us leave us deeply in their debt. Of note is the fact that 10 authors (Carol Baker, Ken Boyer, Jim Cherry, Morven Edwards, Chuck Grose, Scott Halstead, Maggie Hammerschlag, Shelly Kaplan, Ed Mason, and Barbara Stechenberg) have contributed to all eight editions of *Textbook of Pediatric Infectious Diseases*.

Once again, infectious diseases are discussed according to organ systems that may be affected, as well as individually by microorganisms. In all sections in which diseases related to specific agents are discussed,

emphasis has been placed, to the greatest extent possible, on the specificity of clinical manifestations that may be related to the organism causing the disease. Detailed information regarding the best means to establish a diagnosis and explicit recommendations for therapy are provided. In the present era of instant information, we have noted that historical perspectives relating to disease categories, as well as specific agents, are ignored. Because history is an important teacher, we have retained relevant historical details in this eighth edition.

Throughout the 37 years and eight-edition history of the *Textbook of Pediatric Infectious Diseases*, a number of classic chapters exist (e.g., measles, rubella, enteroviruses, and mycoplasma infections). The data in these chapters are unavailable in any other single-source publication.

The entire text of this eighth edition has been revised extensively. The seventh edition contained almost 4000 pages even though we included only new references in the print edition, which is close to the maximum that can be included in a two-volume book. Therefore, with this eighth edition, we were faced with a major dilemma: specifically, how to include new important material that had become available since the seventh edition but not to substantially increase the size of the book. We approached this dilemma in two ways. One problem in previous editions was redundancy, which we have addressed by combining information in some previous separate chapters into more concise single presentations and by shortening some chapters. The second way, which we introduced in the last edition, is to print only new references. The electronic version of the text contains all references.

This edition continues the format that was initiated in the fourth edition, in that infections with specific microorganisms have been organized to provide appropriate emphasis on the common features that may relate specific microorganisms to one another. Thus, all gram-positive coccal organisms are presented sequentially and are followed by gram-negative cocci, gram-positive bacilli, enterobacteria, gram-negative coccobacilli, Treponemataceae, anaerobic bacteria, and so forth. In addition, special sections of the text have been devoted to discussions of each of the following: molecular determinants of microbial pathogenesis; immunologic and phagocytic responses to infection; metabolic response of the host to infections; interaction of infection and nutrition; pathogenesis and treatment of fever; the human microbiome; epidemiology and biostatistics of infectious diseases; infections of the compromised host; Kawasaki disease; chronic fatigue syndrome; international travel issues for children; infectious disease problems of international adoptees and refugees; nosocomial infections; prevention and control of infections in hospitalized children; pharmacology and pharmacokinetics of antibacterial, antiviral, antifungal, and antiparasitic agents; immunomodulating agents; active and passive immunizing agents; public health considerations; infections in day care environments; and use of the bacteriology, mycology, parasitology, virology, and serology laboratories. The section on infections in the compromised host has again been expanded. This expansion has been necessitated by the large number of children, particularly transplant recipients, who have many infectious disease problems and constitute a large part of the consulting practice of many pediatric infectious disease physicians.

With some sadness, we have retained a section on bioterrorism, which is necessitated by the current state of world affairs. The section on immunomodulating agents and their potential use in the treatment of infectious diseases has been expanded because information on this subject has become more extensive since the publication of the last edition. We have also expanded the section on Ebola virus and included a new chapter on Zika virus.

This project could not have been brought to fruition without the help and assistance of many people whose names do not appear in the text. No words are sufficient to adequately convey our gratitude appropriately; we hope that they know they have our heartfelt thanks.

We would like to single out certain individuals for specific mention. First and foremost, we convey our appreciation to Laura Wennstrom Sheehan for the many hours she devoted to this edition. In her spare time between her position as Manager of Research Administration for the UCLA Department of Family Medicine and raising her young daughter, she coordinated the overall process of moving the book forward. She tended to numerous details relating to copyediting, transcribing, references, timing, and communication between the editors and Elsevier. Her expertise in EndNote was invaluable to the authors, editors, and publishing team for the organization of countless references throughout this edition. We are extremely grateful to have her as a part of our team. We would also like to acknowledge the hard work of Jordan Mann who assisted Laura throughout this process.

The following students at UCLA played a key role in processing chapters and in particular helping with references: Lauren M. Nguyen, David Dang, and Jewel Powe. We would also like to thank Nathaniel Wilder Wolf at Baylor who coordinated all the parasite chapters.

Of course this eighth edition of *Textbook of Pediatric Infectious Diseases* would not have been possible without Elsevier. We have been particularly

fortunate to have been able to work with Kate Dimock, Executive Content Strategist, Clinical Solutions at Elsevier throughout the whole process relating to this eighth edition. In addition, the initial planning contribution by Lauren Elise Boyle, Content Development Specialist, was invaluable. This was followed-up by the day-to-day contributions of Margaret Nelson, also a Content Development Specialist at Elsevier. Margaret kept everyone on track in meeting deadlines.

Finally, we thank the Baylor College of Medicine and Texas Children's Hospital in Houston, Texas, the David Geffen School of Medicine at UCLA and the Mattel Children's Hospital UCLA in Los Angeles, California, and Duke University School of Medicine in Durham, North Carolina for providing an environment that is supportive of intellectual pursuits.

Molecular Determinants of Microbial Pathogenesis

David A. Hunstad • Ravi Jhaveri • Audrey R. Odom John • Joseph W. St. Geme III

Despite the availability of a wide variety of antimicrobial agents and expansion of vaccination programs, infectious diseases remain a leading cause of childhood morbidity and mortality worldwide. A number of factors contribute to the increasing importance of infectious agents: rates of antimicrobial resistance continue to rise, global travel has become routine, and the number of individuals with altered immunity has increased. Furthermore, in recent years, microorganisms have been implicated in diseases previously considered noninfectious, and a variety of new, emerging, and reemerging pathogens have been recognized.

Pathogens are defined as microorganisms that are capable of causing disease. However, not all pathogens are equal with respect to their pathogenic potential (i.e., their virulence). Many pathogens are, in fact, commensal organisms that live in harmony with their host under most conditions, causing disease only when normal immune mechanisms are disrupted or absent. Other pathogens produce disease even in the setting of intact host defenses and almost always cause symptoms.

For a given microbe, pathogenic potential is often determined by the genomic content and regulation of virulence-associated genes. Some bacterial species are capable of natural transformation and readily acquire fragments of DNA from other organisms, thus expanding or altering their genetic composition, occasionally with consequences related to virulence or antimicrobial resistance. A number of microorganisms carry virulence-associated genes on mobile genetic elements, including plasmids, transposons, and bacteriophages. These elements may equip the organism with genetic information that facilitates rapid adaptation to an unfavorable or changing environment. Comparison of genomes from pathogenic and nonpathogenic bacteria within a single genus or species has led to the identification of *pathogenicity islands*, which are large blocks of chromosomal DNA that are present in pathogens and absent from related nonpathogens. These blocks are flanked by insertion sequences or repeat elements and differ in nucleotide composition relative to the surrounding genome, suggesting acquisition by horizontal exchange. Pathogenicity islands in bacteria encode a variety of virulence factors, including protein secretion systems, secreted effector molecules, adhesins, and regulatory proteins. In an analogous way, some viral pathogens such as influenza virus are capable of exchanging nucleic acid segments with other viruses, leading to changes in pathogenicity, host tropism, and transmissibility.

To be successful, a pathogen must enter the host, occupy an appropriate niche, and then multiply. Sometimes the pathogen will induce damage to the host and then spread to other tissues, either near the initial site of infection or more distant. Often the pathogen will stop short of causing death to the host, maintaining latent infection or producing symptoms such as cough or diarrhea that facilitate spread to another host. This chapter addresses several key steps in the pathogenic process, each illustrated with examples of pathogens and paradigms of relevance to infectious diseases in children.

COLONIZATION

Most bacterial infections begin with microbial colonization of a host surface, typically the skin, the respiratory tract, the gastrointestinal tract, or the genitourinary tract. Although colonization is not sufficient for an organism to produce disease, it is a necessary prerequisite. The process of bacterial colonization requires specialized microbial factors, called adhesins, that promote adherence to host structures and enable these organisms to overcome local mechanical defenses such as mucociliary function, peristalsis, and urinary flow. The cognate receptors for these

interactions are generally either carbohydrate or protein structures, in some cases expressed on host cells and in other instances present in mucosal secretions or in submucosal tissue.

Pilus Adhesins

Perhaps most common among bacterial adhesins are hairlike fibers called pili (also called fimbriae). Pili are heteropolymeric protein structures comprised largely of a major subunit usually ranging in size from 15 to 25 kDa. Because of their size and morphology, most pili can be visualized by negative-staining transmission electron microscopy.

The prototype example among adhesive pili is the P (or Pap) pilus, which is expressed by uropathogenic *Escherichia coli* (UPEC) and has been strongly associated with pyelonephritis. P pili recognize globoseries glycolipids, which are host molecules that are characterized by a core structure consisting of Gal- α 1,4-Gal. The globoseries glycolipids are especially abundant in renal epithelium,²⁵ thus accounting for the predilection of P-piliated *E. coli* to adhere to kidney tissue and cause pyelonephritis. Type 1 pili are analogous fibers expressed by UPEC and bind mannosylated uroplakin proteins in the mammalian bladder to initiate cystitis.¹⁵³ As shown in Fig. 1.1, P pili are composite structures and consist of two subassemblies, including a thick rod that emanates from the bacterial surface and a thin tip fibrillum that extends distally.^{173,270} The pilus rod is a right-handed helical cylinder and is composed of repeating PapA subunits, whereas the tip fibrillum has an open helical configuration and contains mostly repeating PapE subunits. The two subassemblies are joined to each other by the PapK adaptor protein. PapG contains the adhesive moiety and is located at the distal end of the tip fibrillum, joined to PapE by the PapF adaptor.¹⁵⁰

P pili are assembled through a canonical process termed the *chaperone-usher pathway* that involves a periplasmic chaperone (PapD) and an outer membrane usher (PapC) (see Fig. 1.1).^{65,174} Subunit proteins (e.g., PapA) are translated in the bacterial cytoplasm, enter the periplasm through the inner membrane Sec machinery, and are stabilized by interaction with the chaperone, which ferries them to the usher. Extrusion of the nascent fiber is controlled by a “plug” domain in the usher pore; because the periplasm is devoid of adenosine triphosphate (ATP), the assembly process is energetically driven by the entropically favorable final conformation of the incorporated subunits.^{189,259} More than 30 different bacterial adhesive structures are assembled via this chaperone-usher pathway, with distinct PapD-like chaperones and PapC-like ushers. The PapD-like chaperones can be divided into two distinct subfamilies based on conserved structural differences that occur near the subunit binding site.¹³⁸ One subfamily is involved in the assembly of rod-like pili similar to P pili, whereas the second subfamily participates in the biogenesis of more atypical filamentous structures, such as Caf1 of *Yersinia pestis* (the plague bacterium), which forms an amorphous “mat” on the bacterial surface. Thus the nature of the chaperone is directly correlated with the architecture of the adhesive appendage that it helps to assemble.²⁸⁵

Type 4 pili represent a second class of pili and are distinguished by a methylated first amino acid (usually phenylalanine); a short, positively charged leader sequence; a conserved hydrophobic N-terminal domain; and a tendency to form bundle-like structures. Type 4 pili have been identified in a number of gram-negative bacterial pathogens, including *Neisseria gonorrhoeae*, *N. meningitidis*, enteropathogenic *E. coli* (EPEC), *Vibrio cholerae*, *Pseudomonas aeruginosa*, *Kingella kingae*, *Eikenella corrodens*, *Haemophilus influenzae*, and *Moraxella* species.^{32,99,193,208,250,256,272,296,323} Although the mechanism of

FIG. 1.1 Biogenesis and structure of *Escherichia coli* P pili. The *pap* gene cluster and the function of each of the gene products are indicated in the lower portion of the figure. Nascent pilin subunits are complexed with the PapD chaperone and added to the base of the developing pilus via the PapC usher. The mature pilus rod is composed of repeating units of PapA; the tip fibrillum contains the adhesin PapG. The ultrastructure of the pilus is shown in the electron micrograph at the left side of the figure. (Courtesy S.J. Hultgren and F.J. Sauer.)

assembly of type 4 pili is still being elucidated, existing data suggest that the process is complex. For example, between 20 and 40 gene products are required for the assembly of *P. aeruginosa* type 4 pili, and at least 15 plasmid-encoded proteins are involved in the biogenesis of EPEC type 4 pili.^{127,294} Based on studies of *P. aeruginosa*, EPEC, *Neisseria*, and *V. cholerae*, the presence of an inner membrane prepilin peptidase appears to be a general prerequisite for type 4 pilus biogenesis.^{161,176,226} Type 4 pili are often glycosylated, with carbohydrate decoration affecting function in at least some cases and perhaps serving to obscure antigenic epitopes.^{33,190,278,319} However, despite marked differences in the assembly pathways for type 4 pili and P pili, shared structural themes exist. For example, gonococcal type 4 pili are composed predominantly of PilE structural subunits polymerized into a helical rod.²³⁵ A minor phase-variable adhesive protein called PilC is displayed at the tip of gonococcal pili and is essential for pilus-mediated binding to epithelial cells.^{154,267} These observations suggest that *N. gonorrhoeae* pili may be composite structures with a tip-associated adhesin, analogous to P pili and other pili assembled by the chaperone-usher pathway.

Although adhesive pili are more prevalent in gram-negative bacteria, they are also found in some gram-positive species. One example is *Streptococcus parasanguinis*, an oral pathogen and a member of the *S. sanguinis* family. This organism binds to calcium phosphate (the primary mineral component of tooth enamel) and also to other oral bacteria, epithelial cells, platelets, and fibronectin. Several adhesins mediate these binding functions, including pili referred to as *long fimbriae*. Based on studies of *S. parasanguinis* strain FW213, long fimbriae are fashioned

primarily from Fap1, a 200-kDa protein that includes an unusually long (50 amino acids) signal sequence and a cell-wall sorting signal typical of other gram-positive bacterial surface proteins.^{338,339} Specific glycosylation of Fap1 appears critical to the adhesive function of this fimbrial protein.^{27,293,337} Interestingly, similar to gram-negative bacterial pili, long fimbriae appear to have a composite structure with a pilus tip. The tip contains an additional adhesin called FimA, which in purified form is capable of blocking bacterial adherence to saliva-coated hydroxyapatite.^{81,231} In work by Burnette-Curley and coworkers, disruption of the *fimA* gene resulted in a 7- to 20-fold reduction in the incidence of endocarditis after intravenous inoculation of rats.²⁹ Other gram-positive organisms capable of expressing pili include *Streptococcus pneumoniae* (a common cause of respiratory tract and invasive disease),^{11,216} *Streptococcus agalactiae* (group B streptococcus; a common cause of neonatal pneumonia, sepsis, and meningitis),^{73,264} and *Enterococcus faecalis* (a cause of endocarditis and urinary tract infections).^{215,277}

Nonpilus Adhesins

Beyond pili, a variety of nonpilus adhesins exist. In most cases, nonpilus adhesins are surface-expressed monomeric or oligomeric proteins, although isolated examples of carbohydrate- and lipid-containing adhesive structures have been identified. In general, these molecules are more difficult to visualize by electron microscopy, reflecting their smaller size. Similar to pili, for the most part nonpilus adhesins can be classified according to their mechanism of secretion and presentation on the bacterial surface.

Among the best-characterized bacterial nonpilus adhesins is filamentous hemagglutinin (FHA), a surface protein expressed by *Bordetella pertussis* and other *Bordetella* species. The export of FHA to the surface of the organism occurs via the so-called two-partner secretion (TPS) pathway, a conserved strategy in which a secreted protein (TpsA) interacts with a cognate outer membrane transporter (TpsB).¹²⁸ In *B. pertussis*, the TpsA-type protein FHA is transported by a TpsB-type outer membrane protein called FhaC, which has β -barrel pore-forming properties and facilitates translocation of FHA across the outer membrane.³³³ Homologous TpsB proteins in other species export the hemolysins of *Serratia marcescens*, *Proteus mirabilis*, and *Haemophilus ducreyi*; the *H. influenzae* heme:hemopexin binding protein (HxuA); and the *H. influenzae* HMW1 and HMW2 adhesins, among others.^{9,46,234,249,287,316} The crystal structure of FhaC reveals a 16-stranded β -barrel that is occluded by an N-terminal α -helix and an extracellular loop and a periplasmic module composed of two polypeptide-transport-associated (POTRA) domains. Functional studies have demonstrated that the N terminus of FHA interacts with the FhaC POTRA 1 domain, illuminating what appears to be a general feature of interactions between TpsA and TpsB proteins.^{39,104}

Examination of purified FHA by transmission electron microscopy and circular dichroism spectroscopy showed that the FHA molecule is 50 nm in length and adopts the shape of a horseshoe nail. It has a globular head, a 37-nm-long shaft that averages 4 nm in width but tapers slightly from the head end, and a small flexible tail (Fig. 1.2).^{157,188} In the crystal structure of the N terminus of FHA (the so-called TPS domain that interacts with FhaC), a series of 19-residue repeat motifs form a β -helix that is central to the overall structure of full-length FHA.⁴⁰ Consistent with its large size, FHA contains at least five separate binding domains, four of which have been localized. The region involved

in adherence to sulfated saccharides has been mapped to the N terminus of the FHA molecule.²⁰⁶ Sulfated saccharides such as heparin and heparan sulfate are a major component of mucus and extracellular matrix in the respiratory tract and are also found on the surface of epithelial cells.^{195,342} The region that recognizes lactosylceramides and promotes adherence to ciliated respiratory epithelial cells and macrophages has been localized to amino acids 1141 to 1279 (the carbohydrate recognition domain).²⁵¹ An arginine-glycine-aspartic acid (RGD) tripeptide is located at amino acids 1097 to 1099 and interacts with leukocyte response integrin (LRI), a leukocyte integrin that stimulates upregulation of complement receptor type 3 (CR3).¹⁴⁶ The C terminus of mature FHA has been demonstrated to interact with epithelial cells and macrophage-like cells and appears to modulate the immune response to *Bordetella* infection.¹⁵⁵ Finally, FHA recognizes CR3 (CD11b/CD18), allowing organisms to be ingested by macrophages without stimulating an oxidative burst.^{258,336} The location of the CR3-binding domain is currently unknown.

A growing number of nonpilus adhesins belong to the so-called autotransporter family. These proteins are synthesized as precursor proteins with three functional domains, including an N-terminal canonical signal sequence, an internal passenger domain, and a C-terminal outer membrane domain. The signal sequence directs the protein to the Sec machinery and is cleaved after it facilitates transport of the polypeptide from the cytoplasm to the periplasm. The C-terminal domain inserts into the outer membrane and forms a β -barrel with a central hydrophilic channel. Ultimately, the passenger domain is presented on the surface of the organism and influences interaction with host molecules.¹²⁰ Recent studies have established that autotransporter proteins can be separated into two distinct groups, designated *conventional autotransporters* and *trimeric autotransporters* (Fig. 1.3).⁵² In conventional autotransporters, the C-terminal outer membrane domain contains roughly 300 amino acids and is a monomeric β -barrel with a single N-terminal α -helix spanning the pore (Fig. 1.4A).^{232,299} In trimeric autotransporters, the C-terminal outer membrane domain contains approximately 70 amino acids and forms heat- and detergent-resistant trimers in the outer membrane. Each trimer forms a β -barrel with four strands from each of the three subunits and with three N-terminal α -helices spanning the pore (Fig. 1.4B).²⁰⁴

One example of a conventional autotransporter adhesin is the *H. influenzae* Hap protein, which was discovered based on its ability to promote adherence and low-level invasion in assays with cultured human epithelial cells.²⁸⁶ Hap also promotes bacterial binding to extracellular matrix proteins and bacterial microcolony formation.^{83,121} Examination of chimeric proteins and studies with purified protein have demonstrated that the adhesive activity responsible for Hap-mediated adherence, invasion, binding to extracellular matrix proteins, and microcolony formation localizes to the passenger domain, referred to as Hap_s.^{83,121} More detailed characterization of Hap_s has established that the region responsible for interaction with host epithelial cells and microcolony formation resides in the C-terminal 311 amino acids and may have utility as a vaccine antigen.^{57,82,183} This region folds into a triangular prism-like structure that can mediate Hap-Hap dimerization and higher degrees of multimerization, thus facilitating interbacterial interaction and microcolony formation.²⁰² A prototype member of the trimeric autotransporter subfamily is the *H. influenzae* Hia adhesin. This protein is expressed in a subset of nontypable *H. influenzae* strains and contains two homologous high-affinity trimeric binding domains, creating the potential for stable multivalent interaction with respiratory epithelial cells.^{175,203,343}

Another group of nonpilus adhesins is typified by intimin, a protein expressed by enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), and the murine pathogen *Citrobacter rodentium*. Intimin contains a flexible N terminus, a central β -barrel domain that integrates into the outer membrane, and a C-terminal binding domain that interacts with the translocated intimin receptor (Tir).³¹¹ Tir is an interesting example of a pathogen-derived receptor that is inserted into target host cells. After initial cell attachment mediated by type 4 pili, EPEC employs a type III secretion system (discussed in detail later in this chapter) to inject Tir into the host cell cytoplasm,^{164,335} from where it is then inserted into the host cell membrane.²⁵⁴ The subsequent interaction between

FIG. 1.2 Ribbon representation model structure of filamentous hemagglutinin from *Bordetella pertussis*. There are five regions that are assigned β -helical coils, designated B0, R1, B1, R2, and B2. The N terminus of the protein is designated with "N," and the C terminus of the protein is designated with "C." The locations of the sulfated saccharide binding domain, the carbohydrate recognition domain, and the RGD tripeptide are noted. (From Kajava AV, Cheng N, Cleaver R, et al. Beta-helix model for the filamentous haemagglutinin adhesin of *Bordetella pertussis* and related bacterial secretory proteins. *Mol Microbiol.* 2001;42:279–92.)

FIG. 1.3 Autotransporter protein secretion pathway. Conventional autotransporter secretion is shown on the left, and trimeric autotransporter secretion is shown on the right. Autotransporter proteins are synthesized as preproteins with three functional domains, including an N-terminal signal sequence (shown in green), an internal passenger domain (shown in red), and a C-terminal outer membrane β -barrel domain (shown in blue). IM indicates inner membrane, and OM indicates outer membrane. Protein secretion begins with export of the protein from the cytoplasm via the inner membrane Sec machinery (Sec). Most conventional autotransporters are cleaved on the bacterial surface. (From Cotter SE, Surana NK, St Geme JW III. Trimeric autotransporters: a distinct subfamily of autotransporter proteins. *Trends Microbiol.* 2005;13:199–205.)

FIG. 1.4 Crystal structures of the C-terminal outer membrane β -barrel of autotransporter proteins. (A) Crystal structure of NalP, a conventional autotransporter; β strands are shown in shades of blue, and the α -helix that crosses the channel is shown in red. (B) Crystal structure of Hia, a trimeric autotransporter; individual subunits are shown in red, green, and yellow. (A, From Surana NK, Cotter SE, Yeo HJ, et al. Structural determinants of *Haemophilus influenzae* adherence to host epithelium: variations on type V secretion. In: Waksman G, Caparon MG, Hultgren SJ, editors. *Structural Basis of Bacterial Pathogenesis*. Washington, DC: American Society for Microbiology; 2005:129–148. B, From Meng G, Surana NK, St Geme JW III, et al. Structure of the outer membrane translocator domain of the *Haemophilus influenzae* Hia trimeric autotransporter. *EMBO J.* 2006;25:2297–304.)

intimin (on the bacterial surface) and Tir (now present on the host cell surface) triggers receptor clustering, dramatic rearrangement of the actin cytoskeleton, and formation of a distinctive pedestal referred to as an *attaching and effacing (A/E) lesion* (Fig. 1.5).^{164,263} The bacterial genes essential for formation of A/E lesions reside within a 35-kb region of the EPEC chromosome called the locus of enterocyte effacement (LEE), an example of a pathogenicity island.^{70,196} This locus is highly conserved in content and organization across all A/E pathogens and contains the genes encoding intimin, Tir, and the requisite type III secretion system. The interactions of Tir and other type III secreted effectors with host proteins influencing actin polymerization are beginning to be understood.^{265,344} Tir contains domains analogous to host immunoreceptor tyrosine-based inhibition motifs (ITIM) important for regulation of eukaryotic signaling. On this basis, Tir recruits certain host proteins to regulate actin dynamics and inhibit proinflammatory signaling pathways.^{61,266,280,328} Given its central role in EHEC/EPEC pathogenesis and its immunogenicity, intimin is also being examined as a target for the development of antivirulence therapeutics or vaccines in A/E diseases.

In recent years, investigators have identified a large family of nonpilus adhesins involved in adherence to host extracellular matrix proteins including fibronectin, laminin, vitronectin, collagen, fibrinogen, and a variety of proteoglycans. These adhesins have been classified as microbial surface components recognizing adhesive matrix molecules (MSCRAMMs) and are especially prevalent among gram-positive bacteria.²³⁸ In gram-positive organisms these proteins are covalently anchored to the cell wall peptidoglycan and have a characteristic primary amino acid sequence. In particular, the C terminus contains a segment rich in proline and glycine residues, an LPXTG motif (involved in sorting and covalently anchoring the protein to the cell wall), a hydrophobic membrane-spanning domain, and a short positively charged segment that resides in the cytoplasm and serves as a cell wall retention signal. Adhesive functions are typically located near the N terminus.⁸⁵

Staphylococcus aureus is a common gram-positive pathogen in children and is capable of producing a variety of MSCRAMMs, including collagen-binding protein (CNA), fibronectin-binding proteins A and B, and clumping factors A and B. Recent work indicates that although

FIG. 1.5 Enteropathogenic *E. coli* are perched on pedestals in the attaching and effacing lesion. (Courtesy B.B. Finlay; from Rosenshine I, Ruschkowski S, Stein M, et al. A pathogenic bacterium triggers epithelial signals to form a functional bacterial receptor that mediates actin pseudopod formation. *EMBO J.* 1996;15:2613–24.)

these proteins mediate typical binding interactions with host proteins, they are not monospecific, and a given MSCRAMM may bind multiple host connective tissue components or multiple motifs within a single host fiber type.²⁸⁴ In addition, many are capable of provoking platelet activation. *S. aureus* strains recovered from patients with septic arthritis commonly express CNA, which mediates binding to cartilage in vitro and appears to play a key role in the pathogenesis of septic arthritis in experimental mice.^{237,239,300} Fibronectin-binding protein A (FnBPA) shares homology with *S. pyogenes* protein F and mediates binding to fibronectin and the γ chain of fibrinogen, as well as to elastin and tropoelastin.^{162,262,322} Accordingly, this protein is important in *S. aureus* endocarditis²⁴⁷ and in infections of implanted biomaterials, which become coated with fibrinogen and fibrin soon after implantation. Clumping factor (ClfA) was named based on the observation that it mediates bacterial clumping in the presence of soluble fibrinogen.¹⁹⁷ Similar to FnBPA, ClfA mediates binding to fibrinogen-coated surfaces in vitro and probably contributes to infections of artificial surfaces.

Other Mechanisms of Adherence

Candida albicans is a common inhabitant of mucosal surfaces and an important cause of systemic disease, especially in patients with compromised immunity. *Candida* blastospores are capable of efficient adhesion to epithelial cells, leading to budding and division. In addition, germ tube formation occurs, facilitating penetration through the epithelial barrier and then dissemination to distant sites.¹³⁵ In recent years, several candidate *C. albicans* adhesins have been identified.^{10,134,180,346} Of particular interest is a protein called INT1, which shares functional homology with the vertebrate integrin family. Integrins are normally expressed by cells of the human immune system (neutrophils, monocytes, macrophages) and mediate cellular binding and shape-changing functions. Each integrin is a heterodimer of an α chain and a β chain. There are a number of distinct α and β chains, and each combination displays a unique binding specificity. INT1 is an α integrin-like protein that recognizes the RGD sequence of the C3 fragment iC3b on epithelial cells. In vitro assays, short peptides encompassing the RGD sequence are capable of inhibiting *C. albicans* adherence by 50%, confirming that INT1 plays a significant role as an adhesin and suggesting that other adhesins also exist.¹³⁵ Beyond promoting adherence to epithelium, INT1 disguises organisms as leukocytes, allowing evasion of phagocytosis. Of note, introduction of INT1 into *Saccharomyces cerevisiae* confers a

capacity for adherence and also results in germ tube formation, indicating a role for this protein in morphogenesis.^{95,94}

The adhesive properties of *C. albicans* are closely tied to its morphologic state. For example, adherence to buccal epithelial cells is greater by organisms bearing germ tubes than by yeast forms.¹⁶⁹ With this information in mind, Staab and coworkers searched a germ tube cDNA library and identified a putative adhesin called hyphal wall protein 1 (Hwp1) encoded by the *hwp1* gene. Examination of the predicted amino acid sequence of Hwp1 revealed similarity to proteins that are substrates for mammalian transglutaminase enzymes.²⁹⁰ These enzymes form a cornified envelope on squamous epithelial cells (including buccal epithelial cells) by cross-linking relevant substrates.³⁰² Interestingly, the interactions of germ tubes with buccal epithelial cells resist stresses (e.g., heating or treatment with sodium dodecylsulfate) capable of dissociating most typical microbe-host adhesive pairs, and elimination of expression of Hwp1 results in a marked reduction in adhesion to buccal epithelial cells.^{23,289} Thus Hwp1 represents a unique adhesive strategy, employing host transglutaminase enzymes to cross-link Hwp1 (via a glycosylphosphatidylinositol remnant anchor) directly to surface proteins on buccal epithelial cells.²⁸⁸ More recently, Hwp1 has been shown to be important for *Candida* biofilm formation,^{77,220} indicating that a similar mechanism may also support interactions between candidal cells.

TISSUE TROPISM

Most microorganisms demonstrate restriction in the range of hosts, tissues, and cell types that they colonize. This restriction is referred to as *tropism* and generally reflects the specificity of the interaction between a given microbial adhesin and its cognate receptor. Accordingly, tropism is determined by the distribution of the relevant host receptor.

Pili of uropathogenic *E. coli* serve as the platform for presentation of one of three different PapG variants, referred to as class I, class II, and class III PapG. All three variants recognize globoseries glycolipids, but each binds with a distinct specificity to the globoseries glycolipid isotypes. For example, class I PapG preferentially recognizes globotriosylceramide (GbO3, Gal- α 1,4-Gal- β 1,3-Glc-ceramide), class II PapG preferentially recognizes globoside (GbO4, GalNAc- β 1,3-Gal- α 1,4-Gal- β 1,3-Glc-ceramide), and class III PapG preferentially interacts with Forssman antigen (GbO5, GalNAc- α 1,3-GalNAc- β 1,3-Gal- α 1,4-Gal- β 1,3-Glc-ceramide).²⁹⁷ Globoside is the dominant globoseries glycolipid expressed in human kidney, and most human isolates of *E. coli* associated with pyelonephritis express class II PapG. In contrast, Forssman antigen is the most abundant globoseries glycolipid in dog kidney, and more than 50% of canine urinary isolates of *E. coli* express class III PapG.³⁴¹ *E. coli*-expressing P pili with class II PapG are not found as a cause of urinary tract infection in dogs. Thus the specificity of the PapG variant at the tip of the P pilus influences host range, favoring infection of either human or dog.

The crystal structure of class II PapG bound to Gal- α 1,4-Gal was solved by Dodson and coworkers, uncovering the structural basis of PapG binding specificity.⁶⁶ Of particular interest, the PapG receptor binding site is located on the side of the molecule and must be oriented with its N- to C-terminal axis parallel to the host cell membrane to allow docking to the receptor. This orientation may be facilitated by the flexibility inherent in the tip fibrillum. The PapG binding site consists of two regions. The first forms a β -barrel, and the second is composed of a central antiparallel β -sheet that is flanked on one side by two 2-stranded β -sheets and on the other side by an α -helix. When class II PapG interacts with GbO4, the arginine residue at position 170 in PapG makes contact with the GbO4 side chain. Interestingly, in class I PapG, a histidine residue occupies position 170, interfering with potential contact with the GbO4 side chain. Similarly, class II PapG and class III PapG differ in amino acids required for interaction with the GbO5 side chain.⁶⁶

Group A streptococcus (*S. pyogenes*) is a common cause of infections of skin and soft tissue, including impetigo, cellulitis, and necrotizing fasciitis. Adherence to host cells by *S. pyogenes* is influenced by nonpili adhesins called M protein and protein F. M protein forms a fiber and consists of a C-terminal region that anchors the protein in the cell wall,

a coiled-coil rod region extending approximately 50 nm from the cell wall, and a short nonhelical domain extending more distally.⁸⁴ Protein F is a 120-kDa protein that is notable for a tandem repeat element consisting of up to six repeats of 32 to 44 amino acids adjacent to the C terminus.^{112,233} M protein promotes adherence to human keratinocytes via interaction with the CD46 molecule (also called membrane cofactor protein, or MCP), whereas protein F mediates adherence to epidermal Langerhans cells, which are located in the basal layer of the epidermis.^{229,230} Thus both M protein and protein F contribute to group A streptococcal adherence to the skin, but each protein directs interaction with a different population of epidermal cells.

Early studies demonstrated that human immunodeficiency virus type 1 (HIV-1) infects CD4⁺ cells and interacts with the CD4 molecule but that CD4 alone is not sufficient to permit infection. More recent observations have established that a number of host cell chemokine receptors, especially CCR5 and CXCR4, serve as coreceptors for HIV-1 and are required for viral entry into CD4⁺ target cells. These coreceptors appear to influence the cellular tropism displayed by different HIV-1 variants.⁶² All HIV variants are able to replicate in primary T cells, but only some can also replicate in primary macrophages or in immortalized T-cell lines. Asymptomatic HIV-infected individuals carry strains that generally use CCR5 as a coreceptor (termed *M5 strains*) and are non-syncytium-inducing in vitro. Such strains have classically been described as macrophage tropic (M-tropic), but recent experiments have demonstrated that these M5 strains can also infect CD4⁺ T cells and peripheral blood mononuclear cells.²⁴⁵ Rapid viral mutation due to the error-prone HIV polymerase and HIV reverse transcriptase leads to the production within the host of syncytium-inducing, T-cell-tropic (T-tropic) HIV-1 strains, which predominate in the circulation of patients with acquired immunodeficiency syndrome.⁶² These variants are generally restricted to CXCR4 (expressed on T cells) as a coreceptor, although some primary syncytium-inducing variants can use both CCR5 and CXCR4.^{71,79,276} T-tropic, syncytium-inducing strains are characterized by positively charged residues at fixed positions of the V3 loop and changes in charge and length of the V2 region of the viral envelope glycoprotein gp120, which binds to CD4 and coreceptors before viral entry into host cells.^{86,87,106} Thus cellular tropism is closely aligned, but not synonymous, with HIV coreceptor usage.

New HIV-1 infection is selectively established by M-tropic HIV-1 strains, even if the transmitting host harbors more pathogenic non-M-tropic strains as well.^{317,352} CCR5 is also expressed on the surface of rectal and vaginal epithelial cells, which may be sites of initial encounter between HIV-1 and the human host.³⁴⁹ The importance of CCR5 in HIV-1 binding to CD4⁺ cells is underscored by the observation that individuals homozygous for a 32-bp deletion in CCR5 (the $\Delta 32$ allele) are resistant to infection with HIV-1.^{137,184} The $\Delta 32$ heterozygous state does not necessarily protect against HIV-1 acquisition, although HIV disease in heterozygous patients may follow an attenuated course. This allele is surprisingly frequent (10%–14%) in white populations, leading to speculation that it provided a survival advantage during one or more historical epidemics of infectious diseases.²²⁵ However, more recent data suggest that the $\Delta 32$ allele may actually confer immune deficiency in the presence of challenge with certain viral pathogens, such as West Nile virus.^{100,101} Of note, CCR5 may have a role in controlling the development of malignancy, including lymphoma, raising some concern about developing anti-HIV pharmacologic agents that target CCR5 function.¹⁷⁸ Finally, co-evolution of viral determinants and host cell receptors may determine the spectrum of tissue and organ involvement within the host. For example, the chemokine receptor CCR8 may facilitate the entry of neurotropic HIV-1 strains into brain cells,¹⁵² and envelopes derived from brain isolates of HIV are adapted to infect cells with low-level CD4/CCR5 expression, such as neuroglia and brain macrophages.²⁴⁴

Other viruses also demonstrate tropism for specific cells or tissues within the host. Hepatitis C virus (HCV) has been demonstrated to use multiple cell surface molecules in sequence to locate and gain entry into target cells. HCV is bound to low-density lipoprotein (LDL) in serum and first binds to scavenger-receptor B1 (SR-B1), which is enriched on liver cells and serves to bind lipoprotein molecules.³⁴ After this initial binding event, HCV E2 protein interacts with the CD81 molecule, the

critical receptor for free virus.^{159,321,351} Once virus has bound to CD81, this virus-receptor complex traffics to the gap junction, where the virus interacts with two key gap junction proteins, claudin-1 and occludin-1, to enter cells.^{78,114,172} Human occludin-1 recently has been shown to be necessary for HCV entry into mouse cells, an advance that will facilitate disease modeling in the laboratory.²⁴⁸ Although the liver does not exclusively express any of these four molecules, the combination of these four, the structural organization of liver cells, and other yet-undetermined intracellular factors account for the tropism of HCV for the liver.²⁴⁶

Similar observations have been made for coxsackievirus isolates, which bind to the coxsackie-adenovirus receptor (CAR) molecule located in the tight junction for entry into cells.^{12,42,53,158} Brain, heart, and muscle cells are enriched for CAR in the fetal and neonatal period, whereas adult cells from these tissues express significantly lower levels of the receptor.^{131,147} This developmental difference in CAR density is the likely explanation for severe coxsackievirus infections that are disproportionately seen in infants and young children compared with adults. CAR then allows for an interaction with the tight junction that is mediated by occludin-1, which allows for viral co-opting of host trafficking pathways.⁵³

Among eukaryotic pathogens, tissue tropism can also be a major determinant of virulence. Cerebral malaria is a life-threatening consequence of infection with the protozoan parasite *Plasmodium falciparum* and results from adherence of parasite-infected erythrocytes to cerebral vascular endothelium.²⁰⁹ During erythrocyte infection, the malaria parasite exports a variety of surface receptors to the host plasma membrane. The *P. falciparum* erythrocyte membrane protein 1 (PfEMP1) multigene family represents a highly variable set of such receptors, only one variant of which is expressed at any given time. A substantial body of work has established that different forms of PfEMP1 possess distinct tissue adherence patterns.¹⁷¹ Specific classes of PfEMP1 types (Group A DC8 and DC13) are associated with cerebral vascular adherence in vitro and are correlated with severe malaria in clinical populations.^{7,38,177} More recent studies suggest that these PfEMP1 forms mediate adherence through interaction with the endothelial protein C receptor.³¹⁴

BIOFILMS

After attachment to a particular surface, a number of pathogens are capable of forming *biofilms*, which can be defined as structured communities of microbial cells enclosed in a self-produced exopolysaccharide matrix. Although most studies of biofilms have involved a single species, it is likely that biofilms relevant to human infection often involve multiple species sharing the advantages of biofilm existence. Human infections associated with biofilms include dental caries, lower airway infection with *P. aeruginosa* and other organisms in patients with cystic fibrosis, and foreign body infections in patients with prostheses and implanted devices. In addition, biofilm formation likely occurs during osteomyelitis and endocarditis.⁴⁹

P. aeruginosa is a model organism for the study of biofilms and forms pillars of stationary (sessile) bacteria held together by an extracellular polysaccharide called alginate. Interposed among these pillars are channels that facilitate the flow of nutrients and provide pathways for motile (planktonic) organisms to move about (Fig. 1.6A). In experiments directed at defining the early steps of *P. aeruginosa* biofilm formation, O'Toole and Kolter established that flagella are required for initial bacterial attachment, presumably because these appendages promote movement toward the relevant surface. After attachment, type 4 pili and pilus-mediated twitching motility promote formation of microcolonies²²⁷ in which transcription of *algC*, *algD*, and *algU* is activated, resulting in synthesis of alginate.⁵⁹ Pulmonary isolates from patients with cystic fibrosis often form highly mucoid colonies (reflecting expression of alginate) or can form tiny colonies on agar plates, the so-called small-colony variant (SCV) phenotype associated with biofilm formation and increased antibiotic resistance.^{115,116,291}

Development of the complex community present within a biofilm requires intercellular communication to coordinate the metabolic and other activities of members of the community. *P. aeruginosa* employs several identified *quorum-sensing* systems, which involve the production

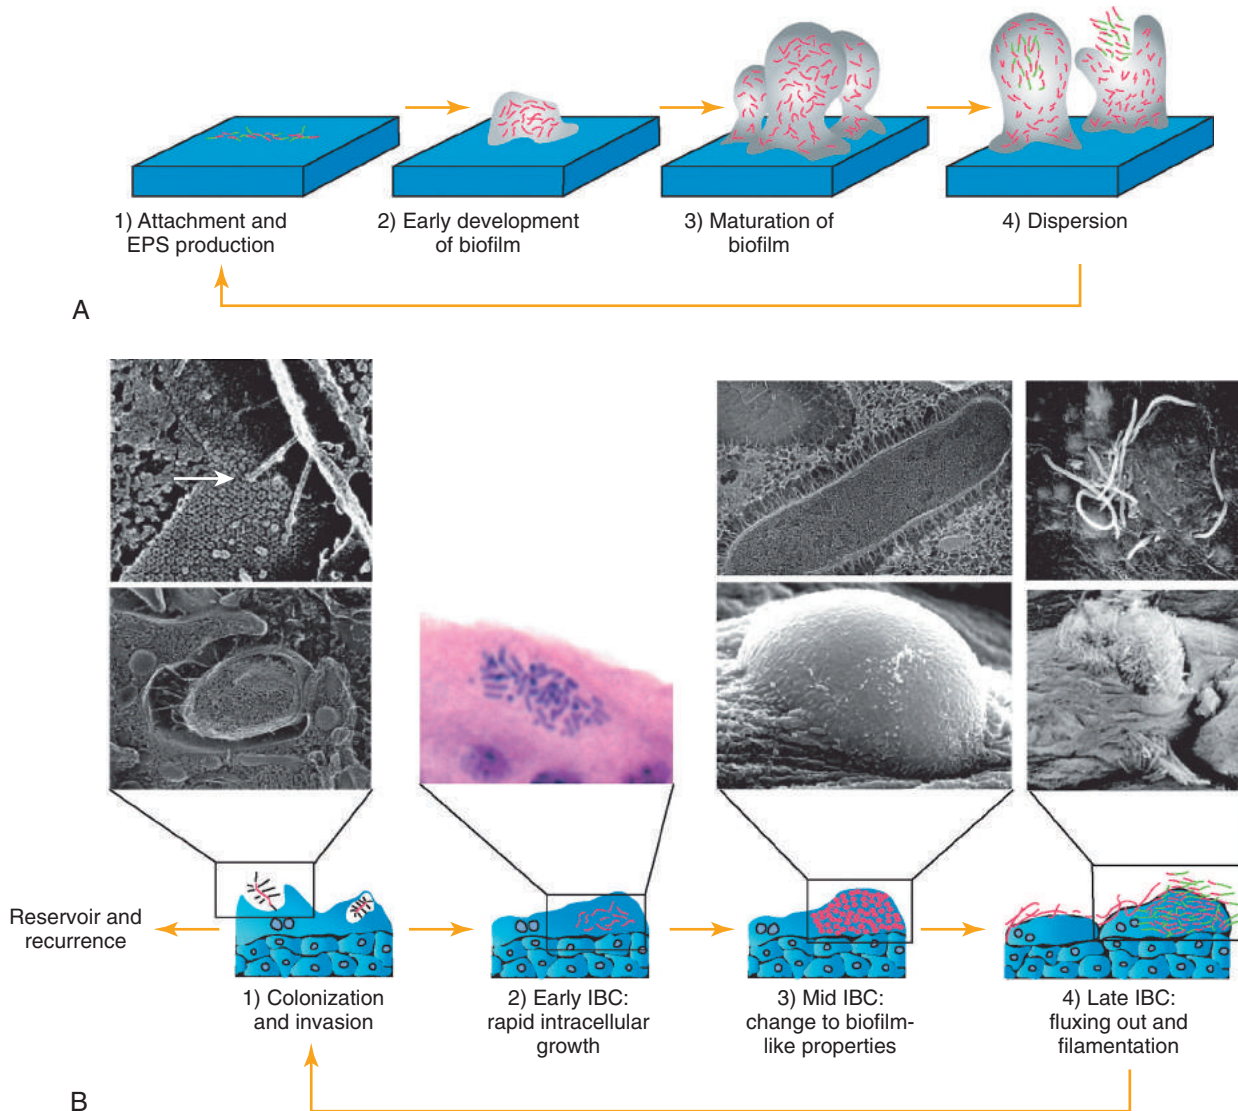

FIG. 1.6 In vitro *Pseudomonas* biofilm formation and parallel stages of formation of uropathogenic *Escherichia coli* intracellular bacterial communities (IBCs). (A) Dynamics of *P. aeruginosa* biofilm formation on an inert surface. Keys to the formation of the biofilm include flagella-mediated attachment, production of exopolysaccharide (EPS), type 4 pilus-based twitching motility, and a quorum sensing system. (B) Composite representation of the stages of IBC formation and maturation. (A, From Costerton JW, Stewart PS, Greenberg EP. Bacterial biofilms: a common cause of persistent infections. *Science*. 1999;284:1318–22, copyright 1999 American Association for the Advancement of Science. B, From Kau AL, Hunstad DA, Hultgren SJ. Interaction of uropathogenic *Escherichia coli* with host uroepithelium. *Curr Opin Microbiol*. 2005;8:54–9.)

of small molecules that are sensed by neighboring organisms and regulate gene expression in these neighbors. One well-studied system is based on the acyl-homoserine lactone called *N*-(3-oxododecanoyl)-L-homoserine lactone (3OC12-HSL).^{60,236} 3OC12-HSL is synthesized in a reaction catalyzed by LasI and accumulates with increases in population density. Ultimately, 3OC12-HSL reaches a critical concentration and then interacts with LasR, serving to activate transcription of a number of genes. Host inflammatory pathways are also induced directly by accumulated 3OC12-HSL.²⁷⁹ Organisms with a mutation in *lasI* are capable of attachment and microcolony formation, but the resulting microcolonies remain thin, undifferentiated, and sensitive to dispersion by detergents. Addition of the missing lactone signal to the *lasI* mutant restores development into structured, thick, biocide-resistant biofilms, as are observed with wild-type organisms.⁶⁰ In vivo, mutation in *lasI* impedes establishment of pulmonary infection in mice.^{242,340}

Biofilms also play a prominent role in human infections with *Candida* species, with examples including oral thrush and catheter-associated infections. Although several pathogenic *Candida* species can form biofilms

in the host, the ultrastructure and the molecular strategies underlying biofilm formation vary from one species to another. *C. albicans* is the best studied *Candida* species and relies on the expression of certain cell wall proteins (including Hwp1),²¹⁹ a regulated yeast-to-hyphal switch described earlier, and quorum-sensing molecules such as *E,E*-farnesol, which represses filamentation and can suppress the growth of other nearby bacterial and fungal species.^{63,133,275}

Biofilms constitute a protected mode of growth that allows survival in a hostile environment—for example, in the presence of host immune mechanisms or antimicrobial agents.⁴⁹ Based on studies of *P. aeruginosa*, sessile bacteria release antigens and stimulate production of antibodies, but these antibodies are ineffective in killing organisms within biofilms.⁴¹ Similarly, sessile *P. aeruginosa* stimulate a diminished oxidative burst and are relatively refractory to phagocytic uptake. In addition, fungi and bacteria within biofilms are resistant to the effects of a number of antimicrobial agents, in part because these agents are unable to diffuse into the biofilm and in part because these organisms may exist in a slow-growing or otherwise protected phenotypic state.⁴⁹ Biofilm-like

microbial communities have also been described within host epithelial cells, as with uropathogenic *E. coli* in the mammalian bladder.⁶ Recently, new approaches to antimicrobial therapy include novel natural products and other small molecules that inhibit quorum-sensing and biofilm formation.^{36,96}

CELL ENTRY AND INTRACELLULAR LIFE

After adherence to a host surface, many pathogenic bacteria are able to invade and survive inside epithelial cells and other nonprofessional phagocytes (i.e., M cells in intestinal Peyer's patches). In addition, some pathogens are able to survive inside professional phagocytes (macrophages and neutrophils). Invasion may represent a mechanism to breach host mucosal barriers and gain access to deeper or more distant tissues. Alternatively, invasion may provide the organism with a special niche (e.g., protecting it from host immune mechanisms). In the case of viruses, cell entry ensures access to the cell machinery required for viral replication.

Generally the process of bacterial invasion involves a class of molecules called invasins that mediate adherence and entry. For many bacteria, invasion is an active event that relies on underlying host cell functions and is associated with rearrangement of the host cell cytoskeleton. Once inside the host cell, the invading or internalized organism usually is localized within a membrane-bound vacuole that contains lysosomal enzymes. In some cases the pathogen escapes from this vacuole and enters the cytoplasm, a more permissive environment. In other cases, the pathogen remains in the vacuole and neutralizes lysosomal enzymatic activity. The processes of invasion into cells, survival within cells, cell-to-cell spread, and entry into the circulation define the extent of infection and dissemination.

Invasion

In considering the molecular mechanism of bacterial invasion, perhaps best characterized are the enteropathogenic *Yersinia* species—namely, *Y. pseudotuberculosis* and *Y. enterocolitica*. These organisms are usually acquired by ingestion of contaminated food or water and typically cause self-limited enteritis or mesenteric adenitis. In infants and other individuals with compromised immunity, they sometimes produce systemic disease. The primary determinant of *Y. pseudotuberculosis* and *Y. enterocolitica* invasion is an adhesive outer membrane protein called invasin, which is encoded by a chromosomal locus called *inv* and binds tightly to a family of $\beta 1$ integrins expressed on host cells, including $\alpha 3 \beta 1$ integrin on the surface of intestinal M cells.¹⁴⁵ The interaction between invasin and $\beta 1$ integrins initiates a cascade of signaling steps in the host cell, resulting in actin rearrangement and formation of large complexes of cytoskeletal elements (talin, vinculin, α -actinin, and others) termed *focal adhesions*.¹⁴⁴ Bacterial entry into the host cell occurs via a “zipper-like” mechanism, with the plasma membrane zipper around the invading organism.

Beyond invasin, two additional proteins called YadA and Ail also influence invasion by enteropathogenic *Yersinia* species. YadA is a 45-kDa surface protein that is encoded by the 70-kb *Yersinia* virulence plasmid. It is highly expressed under environmental conditions (e.g., temperature of 37°C) in which invasion is repressed.⁷⁵ YadA reaches the bacterial surface via the autotransporter pathway and exists in a trimeric form that is essential for its adhesive activity.⁵¹ Like invasin, YadA promotes invasion through binding to $\beta 1$ integrins on the host cell surface, but its binding occurs indirectly via extracellular matrix molecules, including collagens, laminin, and fibronectin.⁷⁶ Based on studies using a mouse oral infection model, in *Y. enterocolitica* YadA is essential for survival and multiplication in Peyer's patches, whereas in *Y. pseudotuberculosis* YadA is dispensable for full virulence.²² Ail is a 17-kDa outer membrane protein that also is encoded by a chromosomal locus (*ail*) and mediates high levels of adherence and low levels of invasion in assays with cultured epithelial cells. In addition, Ail mediates resistance to complement-mediated serum killing, independent of an effect on invasion.¹⁹

Similar to these pathogenic *Yersinia* species, *Listeria monocytogenes* invades epithelial cells via a zipper-like mechanism. Invasion is mediated by proteins called internalin A (InlA) and internalin B (InlB), which are required for virulence in animal models. InlA interacts with

E-cadherin, a host cell transmembrane protein with an intracellular domain that interacts with the cytoskeleton.²⁰⁵ InlB interacts with C1q on host cells and promotes invasion by activating the PI-3 kinase pathway.²⁴ Uropathogenic strains of *E. coli* also invade epithelial cells via a zipper-like mechanism mediated by the FimH adhesin expressed on the tip of type 1 pili. In experiments with cultured bladder epithelial cells, FimH is both necessary and sufficient for entry, as demonstrated by examination of a *fimH*[−] mutant and of latex beads coated with purified FimH.¹⁹⁴ In vitro experiments further suggest that FimH-mediated bacterial binding to a mannose-coated surface may be strengthened by shear forces, such as fluid flow over the surface.^{307,308} After FimH-dependent invasion into superficial epithelial cells of the murine bladder, UPEC multiply rapidly to form intracellular bacterial communities, which display some features of biofilms, including community behavior, differential gene expression, and protection from antimicrobial agents (see Fig. 1.6B).^{6,156,160} A subset of internalized bacteria ultimately form a quiescent bacterial reservoir within the uroepithelium that resists immune clearance and antibiotic therapy and may serve as a seed for recurrent infections.^{139,213,214}

Salmonella enterica serovar *typhimurium* (*S. typhimurium*) is an example of a pathogen that invades cells by a mechanism distinct from zippering. On contact with the epithelial cell surface, *S. typhimurium* triggers a dramatic host cell response characterized by actin rearrangement, calcium and inositol phosphate fluxes, and a “splash” of membrane ruffling surrounding the point of entry. Bacterial internalization into the cell occurs rapidly, with organisms appearing in membrane-bound vacuoles within a few minutes of initial contact with the host cell. The determinants of *S. typhimurium* invasion are encoded by a pathogenicity island called SPI-1, located at centisome 63 on the bacterial chromosome.⁹² Especially important in this region is a prototypical *type III secretion system*, which forms a needle-like complex on the bacterial surface that breaches the host cell membrane and serves to translocate bacterial proteins directly into the host cell, altering the host cell cytoskeleton^{43,186} and influencing immune responses. The base of the needle complex spans both the inner and outer membranes and is about 40 nm in diameter, whereas the needle itself is 8 nm in width and approximately 80 nm in length (Fig. 1.7).^{45,93}

The proteins secreted through the *S. typhimurium* needle complex (and other type III secretion systems) and into the host cell are referred to as *effector proteins*. SopE is an effector protein that mediates the initial rearrangement of actin and ruffling of the host cell membrane. It functions as a guanyl-nucleotide exchange factor (GEF) and activates two host cell Rho GTPase proteins called Rac and Cdc42.^{35,111,113} SptP is an effector protein that functions as an antagonist of SopE, mediating reversal of actin rearrangement by converting Rac and Cdc42 to the inactive forms (GDP forms). Consistent with these functions, SopE and SptP directly antagonize each other when coinjected into cells.⁹¹ Other effector proteins secreted by the *S. typhimurium* SPI-1 type III secretion system include the inositol phosphate phosphorylase SopB, which disrupts normal host cell signaling mechanisms,²²⁴ and AvrA, which interferes with the nuclear factor κB (NF- κB) signaling pathway in host cells, thereby downregulating host inflammatory responses.⁴⁴

Important accessory and regulatory genes are also present within SPI-1. As an example, the *sicA* gene is just upstream of the *sipB* and *sipC* genes and encodes an accessory protein with chaperone activity essential for stabilization and translocation of SipB, SipC, and SopE.³¹³ Other chaperones encoded by SPI-1 are involved in the stabilization and translocation of other effector proteins. The genetic and environmental factors that regulate the expression of type III secretion machinery and secreted proteins represent an area of ongoing study.⁵

In *Plasmodium falciparum*, the mechanisms of both host erythrocyte invasion and immune evasion are tightly linked. A mature parasite may release as many as 32 daughter parasites, called merozoites, into the bloodstream. In less than 30 seconds, merozoites attach to and invade new erythrocytes. High-titer antibodies to invasion proteins, as are present in the serum of semi-immune individuals living in endemic areas, can block these processes. For this reason, the molecular invasion machinery of *P. falciparum* is of considerable interest for vaccine development.^{240,303} The initial contact between *Plasmodium* merozoites and host erythrocytes is weak and is thought to be mediated through

FIG. 1.7 General structure of the gram-negative type III secretion system, according to electron micrographic and other data. Represented are (A) electron micrographs of isolated needle complexes, (B) cross-sectional schematic of the components of the needle complex, and (C) surface views of the assembly. (From Galan JE, Wolf-Watz H. Protein delivery into eukaryotic cells by type III secretion machines. *Nature*. 2006;444:567–73.)

merozoite surface proteins (MSPs) present along the entire merozoite surface. Stronger interactions are mediated by several additional receptors, notably the erythrocyte binding antigens EBA-175 and EBA-140, which engage the erythrocyte-specific receptors glycophorin A and glycophorin B, respectively. Recently, an additional parasite protein called PfRH5 was recognized as an indispensable mediator of parasite invasion via interaction with the human receptor basigin.⁵⁴ Anti-RH5 antisera have potent invasion-inhibiting activities,³¹² and an RH5-based vaccine showed efficacy in an *Aotus* monkey infection model.⁷² On the basis of these data, PfRH5 has emerged as a strong candidate vaccine antigen to prevent severe malaria.

Intracellular Survival

Once an organism invades a nonprofessional phagocyte or is ingested by a professional phagocyte, several potential outcomes exist. Often, the organism is killed. However, some pathogens have developed strategies to survive and replicate inside host cells, in some cases within a vacuole and in others by escaping from the vacuole.

There is general agreement that *S. typhimurium* resides within a membrane-bound vacuole in both professional and nonprofessional phagocytes. However, the vacuole lacks several lysosomal markers typical of the main endocytic pathway (the mannose-6-phosphate receptor pathway) and appears to be distinct from this pathway. Insight into the molecular determinants of intravacuolar survival came when two independent groups reported the discovery of a second *Salmonella* pathogenicity island, now called SPI-2.^{122,228} This island maps to centisome 31 and encodes another type III secretion system, including structural proteins (*ssa* locus),¹²² effector proteins (*sse* locus), and accessory proteins (*ssc* locus). In addition, this region encodes a two-component regulatory system consisting of a membrane-located sensor kinase (SsrA) and a

transcriptional regulator (SsrB).²²⁸ Mutations in SPI-2 result in reduced survival inside macrophages, with no effect on adherence and invasion in assays with intestinal epithelial cells.²²⁸ *Salmonella* SPI-2 mutants demonstrate reduced virulence in experimental mice (up to a 104-fold reduction in 50% lethal dose), suggesting that survival inside macrophages is a key factor in the pathogenesis of disease.²⁷³ Expression of SPI-2 genes within the macrophage vacuole depends at least in part on the acidic intravacuolar environment. Inhibition of macrophage vacuolar acidification using bafilomycin A1 (an inhibitor of the vacuolar proton ATPase) results in a sharp attenuation in transcription of SPI-2 genes. This effect is not reproduced by low pH alone outside the vacuole, suggesting that other environmental effects within the vacuole influence SPI-2 expression.³⁷ Recent work indicates that *Salmonella* SPI-2 transcription is activated before invasion, apparently preparing the pathogen for the hostile intracellular environment.²⁶ As a group, the SPI-2 genes appear to modulate host endocytic and exocytic transport mechanisms and inflammatory signaling.^{1,142}

A third *Salmonella* pathogenicity island called SPI-3 also promotes survival inside macrophages. This island is located at centisome 82 and was discovered by examining the *Salmonella* *selC* locus, a tRNA gene where pathogenicity islands reside in some strains of *E. coli*.^{15,17} SPI-3 contains the *mgtBC* operon, which permits *S. typhimurium* growth in environments with low concentrations of Mg²⁺, including macrophages. In particular, mutation of the *mgtBC* operon abolishes the ability of *S. typhimurium* to replicate in low-Mg²⁺ liquid media and in macrophages, and addition of Mg²⁺ to the medium after phagocytosis restores the ability to survive intracellularly. Homologous *mgtBC* genes have been found in other organisms with intracellular lifestyles, such as *Brucella melitensis* and *Yersinia pestis*.¹⁶ In *Salmonella*, the *mgtBC* genes are expressed after internalization into host cells under control of the

PhoP-PhoQ two-component regulatory system, a complex that directs expression of a number of virulence determinants.¹⁹¹

The ability to survive within phagocytic cells may provide *Salmonella* with a means to exploit an intrinsic host pathway and disseminate to distant sites. In particular, certain phagocytes express the $\beta 2$ integrin CD18, which mediates leukocyte migration in response to various stimuli. During *S. typhimurium* infection, CD18-expressing phagocytes carry organisms from the intestine to the spleen. Indeed, bacterial loads in the liver and spleen are reduced after oral inoculation in CD18-deficient mice when compared with infection in wild-type mice.³¹⁸ On the one hand, this function of CD18 facilitates initiation of a systemic immune response and benefits the host. However, at the same time, it provides bacteria with a mechanism of transit from the gut to organs of the reticuloendothelial system and elsewhere.

Mycobacterium tuberculosis is another intracellular pathogen, and it uses an array of mechanisms to ensure intracellular survival. The *M. tuberculosis* vacuole lacks the usual amounts of the vesicular proton ATPase responsible for mediating acidification and fails to acidify to normal levels.²⁹⁸ In addition, *M. tuberculosis* blocks fusion of the vacuole with acidic lysosomes, further preventing acidification.²⁶⁸ Similar to intracellular gram-negative bacterial pathogens, *M. tuberculosis* contains an *mgcC* gene, and mutation of this gene results in impaired virulence in cultured human macrophages and in mouse spleen and lung. Low Mg^{2+} concentration and mildly acidic pH inhibit the growth of the *mgcC* mutant, suggesting that the gene is important for survival in the phagosome, where such conditions may exist.²⁸ Another factor that influences *M. tuberculosis* survival within macrophages is isocitrate lyase, an enzyme of the glycolytic shunt that is essential for metabolism of fatty acids. Expression of isocitrate lyase is upregulated during infection of activated macrophages and is required for full virulence in a murine model of infection, independent of an effect on bacterial growth.¹⁹⁸ The crystal structure of *M. tuberculosis* isocitrate lyase has been solved and may provide a target for new drug therapies against persistent infection because this enzyme is absent from vertebrates.^{271,282}

During the course of interaction with macrophages, *M. tuberculosis* (at a low to moderate multiplicity of infection) is capable of stimulating caspase-1 and inducing macrophage apoptosis. Interestingly, less virulent strains of *M. tuberculosis* are more potent inducers of apoptosis, perhaps resulting in benefit to the host by preventing systemic spread of infection.¹⁶³ At the same time *M. tuberculosis* possesses at least two anti-apoptotic mechanisms that further influence the outcome of macrophage encounters. First, *M. tuberculosis* infection enhances host macrophage production of soluble TNFR2, a protein that binds to tumor necrosis factor alpha (TNF α) and interferes with apoptosis.⁸ Second, *M. tuberculosis* infection activates production of NF- κ B, a transcriptional regulator that activates anti-apoptotic pathways within the host cell.⁹⁷ Of note, higher multiplicities of infection with virulent strains of *M. tuberculosis* can induce caspase-independent cell death in macrophages, a mechanism proposed to contribute to the formation of necrotic lesions during tuberculous disease.¹⁷⁹

L. monocytogenes is an example of an organism that escapes from the phagocytic vacuole in macrophages and epithelial cells and moves into the cytoplasm. This organism causes meningitis and focal brain abscesses in humans and exhibits tropism for the fetoplacental unit. In pregnant women, listeriosis results in fetal loss in 30% of cases. Intravacuolar replication and escape from the vacuole are dependent on listeriolysin O, a hemolysin encoded by the *hly* gene.¹³ Listeriolysin O interacts with cholesterol in host cell membranes and forms pores, leading to lysis of the phagosome.⁹⁰ Host enzymatic activities may also contribute to *Listeria* escape from the phagosome. In human epithelial cells the contributions of a broad-range phospholipase C (called PC-PLC) and a metalloproteinase called Mpl are most important for vacuolar escape in the absence of listeriolysin O.^{107,192,281}

Intracellular survival of the protozoan parasite *Toxoplasma gondii* is thought to rely on parasite virulence factors that directly counter innate host defenses. In mice, interferon gamma (IFN γ) production is required to limit replication of *T. gondii*, in part through induction of immunity-related GTPases (IRGs). In mammalian cells, successful *T. gondii* strains replicate within a protected parasitophorous vacuole (PV) that does not fuse to the host lysosome. During infection with relatively

nonpathogenic parasites, recruitment of IRGs to the PV results in disruption of the PV and parasite death. In contrast, highly pathogenic *T. gondii* express an active serine-threonine kinase called ROP18, which is exported into the host cytoplasm and prevents the recruitment of IRGs.^{140,301} The ROP kinase family is highly expanded in *T. gondii*, comprising 44 other proteins, many of which lack critical catalytic residues and are thought to function as regulatory “pseudokinases.” Interestingly, ROP kinases are absent from the related apicomplexan *Plasmodium* spp., presumably because prevention of IRG recruitment is unnecessary within the protected niche of the host erythrocyte.

Viral Cell Entry

Viruses have developed a specialized family of proteins that specifically function to engage host cell proteins and fuse with cell membranes and that allow for transfer of viral genetic material. The details regarding structure and function of these proteins are reviewed elsewhere.¹⁶⁸ There are two known classes of viral fusion proteins: class I proteins form a hairpin structure with a known α -helix domain (e.g., HIV gp41, influenza HA2), and class II proteins exist in β -sheets and transition from a moderately stable dimeric form to a very stable trimer (e.g., dengue E protein). These fusion proteins undergo conformational changes when transitioning from the prefusion to the postfusion state, resulting in a more stable form that favors the process of viral fusion and entry.

Cell-to-Cell Spread

Movement from one cell to another may help an organism gain a stronger foothold in host tissues. *L. monocytogenes* is one example of a pathogen capable of cell-to-cell spread. Once this organism is free in the cytoplasm, actin begins to polymerize on the bacterial surface. Eventually the condensed actin forms a polar tail or comet, which propels the organism through the cytoplasm and into adjacent cells. The rate of bacterial movement within a cell correlates with actin tail length.³⁰⁵ Actin accumulation and condensation is mediated by the *L. monocytogenes* ActA protein, which is tightly anchored to the bacterial surface and is expressed asymmetrically over the length of the organism.^{283,304} ActA is the sole *Listeria* factor required for actin polymerization because actin tails form in *Xenopus* cytoplasmic extracts containing ActA-coated beads. However, in these experiments, motility occurs only when ActA is distributed asymmetrically on the beads.³⁰ ActA appears to interact directly with actin and also with a variety of other host cytoskeletal proteins.^{90,306} Cytochalasin D is an inhibitor of actin polymerization and inhibits the cell-to-cell spread of *L. monocytogenes* in epithelial monolayers.^{58,210}

On reaching the plasma membrane, bacteria protrude from the cell in filopodium-like structures (called listeriopods), which are then engulfed by neighboring cells. This engulfment may be part of a normal host process because MDCK cells demonstrate low-level endocytosis of adjacent cell membrane fragments even in the absence of bacteria.²⁶¹ The formation of listeriopods and the engulfment of these structures by neighboring cells are independent of listeriolysin O, PI-PLC, and PC-PLC.⁹⁸ Once inside a nascently infected cell, *Listeria* escapes from the double-membrane vacuole via the action of PI-PLC, PC-PLC, and Mpl.⁹⁰ On arrival in the cytosol, bacteria can enter another cycle of actin-based motility and cell-to-cell spread, although one or two bacterial generations may be necessary to regain motility.²⁶¹

A second pathogen capable of actin-based motility and cell-to-cell spread is *Shigella flexneri*. In *Shigella*, a single protein called IcsA is sufficient to induce formation of an actin tail, similar to that observed in *L. monocytogenes*. IcsA is an autotransporter protein that is encoded on the *Shigella* virulence plasmid and is distributed on the bacterial surface in a polarized fashion, possibly as a result of specialized machinery for autotransporter protein secretion near the poles of some gram-negative bacteria.¹⁵¹ Initially, IcsA is distributed over the whole bacterial surface, with a predominance at one pole. However, over time a secreted bacterial protease called IcsP cleaves roughly half of the surface IcsA, mostly at the opposite pole, further polarizing distribution.^{74,292} Elimination of expression of IcsP leads to increased quantities of IcsA and increased actin-based motility, suggesting that IcsA (rather than host factors) is rate limiting in the motility process.²⁷⁴ Like ActA, IcsA is necessary and sufficient to induce polymerization of the actin tail, and

the tail forms at the end where IcsA concentration is highest.¹⁰² Despite the functional similarities between IcsA and ActA, there is no significant sequence homology between the two proteins. In contrast to ActA, no direct interaction between IcsA and actin has been demonstrated, and IcsA is found throughout the actin tail, not only at the bacterial pole-actin tail junction.

When considering cell-to-cell spread of viruses, it is helpful to return to the example of HCV. Claudin-1 and occludin-1 are the gap junction proteins that serve as the final entry point for this virus.^{78,248} It has been demonstrated that HCV can infect neighboring liver cells directly via these gap junction proteins, likely bypassing the extracellular release of virus and subsequent SR-B1 and CD81 binding steps.³⁰⁹ Experiments have demonstrated that antibodies blocking the E2-CD81 interaction inhibit infection from virus-infected media but do not affect infection of naïve cells when co-cultured with previously HCV-infected cells.³⁰⁹ It has also been shown that after infecting a liver cell, HCV promotes breakdown of typical apical to basal organization of liver cells, exposing the gap junction complexes and presumably facilitating cell-to-cell spread.^{199,200}

DAMAGE TO THE HOST

Damage to host cells and host tissues represents a fundamental mechanism by which a pathogen is able to survive at a given site and then spread within a host. Generally, damage is induced by microbial toxins. Most toxins are released extracellularly and are capable of inducing damage at very low concentrations (*exotoxins*). Microbial attachment and invasion facilitate toxin delivery to target cells and target tissues and serve to enhance toxicity.

Historically, microbial toxins have been classified according to a variety of criteria, including cellular target of action (e.g., enterotoxins, leukotoxins, neurotoxins), mechanism of action (e.g., adenosine diphosphate [ADP]-ribosylating toxins, adenylate cyclase toxins, pore-forming toxins, proteolytic toxins), and major biologic effect (e.g., hemolytic toxins, edema-producing toxins). In recent years the term *toxin* has been applied more broadly to include enzymes that mediate damaging effects via phospholipase or hyaluronidase activity.

Bordetella pertussis Toxins

Whooping cough (*B. pertussis* infection) is a classic example of a toxin-mediated disease and involves the interplay of multiple toxins.¹⁶⁵ The pathogenesis of whooping cough begins with *B. pertussis* colonization of the trachea, which is facilitated by a molecule called tracheal cytotoxin (TCT). TCT is a naturally occurring disaccharide-tetrapeptide fragment of peptidoglycan and belongs to the family of muramyl peptides.¹⁰³ Many gram-negative organisms produce an analogous fragment during normal turnover of cell wall components, but significant extracellular release appears to occur only in *Bordetella* species and gonococci. In most other species an inner membrane protein called AmpG recycles this fragment back into the bacterial cell.⁵⁰ TCT is toxic to tracheal epithelial cells in vitro, stimulating nitric oxide synthase and local production of interleukin-1 and causing inhibition of ciliary motility, inhibition of DNA synthesis, and cell death.^{117–119,124} During natural infection, TCT is thought to paralyze the mucociliary escalator and thereby interfere with clearance of *B. pertussis* and respiratory mucus.

Pertussis toxin is believed to be a key determinant of the clinical manifestations of whooping cough. This toxin belongs to a family of bacterial ADP-ribosyltransferase enzymes. The target of pertussis toxin is host cell G proteins, resulting in disruption of normal signaling processes. A number of biologic effects have been ascribed to pertussis toxin, including induction of lymphocytosis, stimulation of insulin release, sensitization to histamine, and disruption of phagocytic cell function; however, the specific relationship between the effects of pertussis toxin and the symptoms of whooping cough remains unclear.¹²⁵ Of note, *B. parapertussis* is closely related to *B. pertussis* and produces a similar cough illness but fails to produce pertussis toxin because of mutations in the *ptx* promoter region.²¹⁸

B. pertussis also elaborates a toxin called adenylate cyclase toxin (CyaA), a member of the RTX (repeat-in-toxin) family of bacterial cytotoxins whose prototype is the *E. coli* hemolysin HlyA.⁵⁰ These toxins

cause target cell lysis by creating pores in the host cell plasma membrane, but at sublytic concentrations many of these toxins also manipulate host enzymatic and signaling pathways within the host cell. In the case of *B. pertussis*, CyaA inhibits host adenylate cyclase, resulting in accumulation of cyclic adenosine monophosphate (cAMP); elevated levels of cAMP within phagocytic cells inhibit oxidative activity and induce apoptosis, thus disabling this arm of the immune system.^{166,167,243} In respiratory epithelial cells, elevated cAMP may result in increased fluid and mucus secretion, further impairing mucociliary function.

Among other examples of these dual-function RTX toxins, the prototypic HlyA of uropathogenic *E. coli* induces the degradation of host actin-associated proteins, resulting in exfoliation of the superficial epithelial layer in the bladder.⁶⁴ The α -hemolysin of contemporary community-associated *S. aureus* strains activates a host epithelial cell surface molecule called ADAM10, which cleaves E-cadherin at cell-cell junctions to permit access of the pathogen across the epithelial layer.^{143,332}

Hemolytic-Uremic Syndrome and Shiga Toxins

A number of intestinal pathogens produce Shiga toxins, including *Shigella dysenteriae*, enterohemorrhagic *E. coli* (including *E. coli* O157:H7), and *Citrobacter freundii*, among others. Shiga toxins are classic A-B toxins, consisting of an A subunit that has toxic activity and five B subunits arranged in a pentameric ring-like structure that promotes binding to host cells and delivery of the A subunit. The B subunits interact with host cell globoseries glycolipids, especially the Pk trisaccharide moiety of globotriaosylceramide (GbO3). The A subunit is endocytosed by the host cell and traverses the cytoplasm in membrane-bound vesicles. Some of these vesicles travel in a retrograde fashion to the Golgi apparatus and then to the endoplasmic reticulum.²⁶⁹ Shiga toxin then co-opts the function of the endoplasmic reticulum proteins HEDJ and BiP to enter the cytosol, where it enzymatically inhibits host 28S ribosomal RNA by cleaving a single adenine residue, resulting in inhibition of protein synthesis and cell death.^{269,347}

In humans, *E. coli* O157:H7 is an important cause of hemorrhagic colitis and sometimes produces hemolytic-uremic syndrome. Infection begins with adherence to epithelial cells via intimin and other proteins encoded by the locus of enterocyte effacement (LEE), resulting in formation of attaching and effacing lesions analogous to those observed in EPEC infection.¹⁹⁶ After adherence, the organism releases Shiga toxin, which traverses the intestinal epithelial cell and enters the bloodstream.² Toxin circulates to distant organs and mediates damage via toxicity to endothelium. Diarrhea likely results from damage to endothelium in small mesenteric vessels, leading to ischemia and sloughing of the intestinal mucosa. The renal effects observed in human hemolytic-uremic syndrome arise from microvascular and glomerular damage with luminal occlusion by fibrin and platelets.³⁵³ Hemolysis and thrombocytopenia likely develop as a consequence of microangiopathy.

Tissue-Degrading Toxins

A number of toxins have enzymatic activity and are capable of degrading tissue components. One example is hyaluronidase, which degrades hyaluronic acid, a repeating disaccharide glycosaminoglycan involved in cell motility, adhesion, and proliferation in normal hosts. Hyaluronic acid contains alternating *N*-acetylglucosamine and glucuronic acid moieties, connected by β linkages. It is prominent in extracellular matrix when cell turnover and tissue repair are prominent—for example, in embryogenesis, wound healing, and carcinogenesis.⁵⁵ The primary host receptor for hyaluronic acid is CD44, which undergoes post-translational modification that varies according to host cell type. Interactions between hyaluronic acid and CD44 are critical to T- and B-cell stimulation, growth of certain lymphoid malignancies, and propagation of certain inflammatory responses.²⁰⁷

In *S. pyogenes*, hyaluronidase is a 96-kDa protein that is encoded by the *hlyA* gene and is released extracellularly. It is proposed to promote invasion through cell layers and tissue planes and is considered one of several *S. pyogenes* spreading factors.¹⁴¹ Interestingly, *S. pyogenes* also produces a thick “capsule” of hyaluronic acid that can interact with other host cellular and extracellular matrix proteins to contribute to tissue invasion by the organism. Other pathogens that produce a hyaluronidase include *S. agalactiae* (group B streptococcus),

Treponema pallidum, *Candida* spp., *Entamoeba histolytica*, and *Ancylostoma braziliense*.⁵⁵

EVASION OF IMMUNITY

To survive and replicate within the host, a pathogen must evade the host immune system. Initially the organism must circumvent innate immune mechanisms, including mechanical forces, resident phagocytes, and complement activity. Over time the organism must overcome adaptive immunity as well, including the presence of specific antibodies.

Antiphagocytic Factors

As described earlier in this chapter, invasion-mediated entry into M cells plays an important role in the early stages of *Yersinia* infection. At the same time, evasion of phagocytosis is critical to the pathogenesis of *Yersinia* disease. The ability to avoid phagocytosis is dependent on the *Yersinia* virulence plasmid, which encodes a number of proteins called Yops.^{48,295} Both YopE and YopH interfere with ingestion by macrophages and neutrophils via slightly different mechanisms. YopE shares sequence homology with the *Salmonella typhimurium* SptP protein and down-regulates all three of the Rho GTPases (Rho, Cdc42, and Rac), thus inhibiting actin rearrangement and blocking formation of membrane ruffles (lamellipodia) and spikes (filopodia).^{3,19} YopH is a protein tyrosine phosphorylase that appears to act on a host cell cytosolic protein called Cas, interfering with recruitment of Rho, Cdc42, and Rac and preventing formation of actin stress fibers, focal complexes, and focal adhesions.^{14,18} YopJ is an acetyltransferase that covalently modifies and inactivates intermediate kinases in the mitogen-activated protein kinase and NF- κ B signaling pathways, leading to host cell apoptosis.^{212,345} Importantly some Yop effectors also represent important immunogens; for example, the immunodominant epitope of YopE represents a major CD8⁺ T-cell antigen in experimental plague and may facilitate a new direction in *Yersinia* vaccine development.^{182,350}

Shigella employs another strategy to induce apoptosis in phagocytic cells. This pathogen produces hemorrhagic enterocolitis and is an important cause of bloody diarrhea in children. Infection begins with ingestion of organisms, which attach to intestinal M cells and then cross the intestinal epithelium.³⁵⁶ On entry into the subepithelial space, organisms are engulfed by resident macrophages and contained in membrane-bound vacuoles. However, they quickly escape from macrophage vacuoles and move to the cytosol of the cell, where they induce apoptosis.³⁵⁵ The mechanism of apoptosis involves a protein called IpaB, which is encoded by the *Shigella* virulence plasmid and is injected into host cell membranes via the *Shigella* type III secretion system.²⁰ Work by Zychlinsky and coworkers showed that IpaB binds to cytosolic interleukin-1 β converting enzyme (caspase-1), a cysteine protease that cleaves IL-1 β to its active form.¹²⁶ Of note, the *S. typhimurium* SipB protein shares homology with IpaB and also induces apoptosis by interacting with caspase-1.¹²³ Interestingly, recent work has shown that IpaB has contrasting effects in epithelial cells, binding to the cell-cycle regulator Mad2L2 to inhibit epithelial turnover and promoting epithelial colonization with *Shigella*.¹⁴⁸

Evasion of Complement Activity

S. pyogenes expresses at least three factors that interfere with host complement activity. Perhaps best known is M protein, which inhibits activation of the alternative complement pathway. This effect is mediated at least in part by the ability of M protein to bind complement factor H, a regulatory protein that inhibits assembly and accelerates decay of C3bBb. Recent studies indicate that serotype M1 and M57 strains express an extracellular protein called Sic (streptococcal inhibitor of complement-mediated lysis), which associates with human plasma proteins called clusterin and histidine-rich glycoprotein (HRG) and apparently blocks formation of the membrane attack complex (C5b-C9).⁴ Studies of epidemic waves of M1 infection demonstrate that Sic undergoes significant variation over time, perhaps in response to the selective pressure associated with specific antibodies.^{129,130,201} Of note, nonpolar inactivation of *sic* results in reduced mucosal colonization of mice.¹⁸⁵ In addition, *S. pyogenes* produces a serine protease called C5a peptidase,

which cleaves and inactivates C5a.³³⁰ C5a is a cleavage product of C5 and serves as a powerful chemoattractant for neutrophils; thus, streptococcal C5a peptidase serves to attenuate the neutrophil response to infection.

N. gonorrhoeae is a common cause of cervicitis, urethritis, and pelvic inflammatory disease and is also capable of producing disseminated disease. Recent spread of antibiotic resistance in this pathogen highlights the need for understanding its pathogenic mechanisms to develop new mitigating strategies. Resistance to complement-mediated killing is important in gonococcal pathogenesis and is due in part to sialylation of lipo-oligosaccharide (LOS), which involves addition of host-derived cytidine monophospho-*N*-acetylneuraminic acid (CMP-NANA) by a bacterial sialyltransferase. Given the requirement for CMP-NANA, subcultivation in the absence of human serum or human neutrophils is associated with loss of sialylation and loss of resistance. Sialylated LOS binds factor H, resulting in downregulation of activity of the alternative pathway C3 convertase. In addition, sialylated LOS interferes with neutrophil phagocytosis and with the normal oxidative burst in neutrophils.^{260,329} A second determinant of resistance to complement-mediated killing is Por1, an outer membrane porin protein that binds both factor H and C4b binding protein (C4b BP).²⁵⁵ C4b BP binds C4b and serves to inhibit assembly and accelerate decay of C4b2a, the classical pathway C3 convertase. Gonococci also produce a third factor that influences resistance to complement—namely, an outer membrane-expressed nitrite reductase called AniA.^{21,31}

Evasion of Humoral Immunity

A number of pathogens have evolved mechanisms to vary surface-exposed immunogenic molecules, thus facilitating evasion of a specific antibody response. *Antigenic variation* represents one such mechanism and is characterized by the emergence of modified molecules with novel antigenic properties. *Phase variation* represents a second such mechanism and is typified by the reversible loss or gain of a given molecule or structure.

N. gonorrhoeae is capable of producing recurrent infection, reflecting the fact that the antibody response to infection fails to provide lasting immunity. In this context, it is noteworthy that *N. gonorrhoeae* pili are an important target of serum antibody and undergo frequent antigenic variation. Gonococcal pilin expression is controlled by the *pilE* locus (the expression locus), which contains an intact pilin gene along with promoter sequences. In addition to *pilE*, the gonococcal chromosome contains numerous copies of variant *pil* sequences, called *pilS* loci.¹¹⁰ These loci are transcriptionally inactive because they lack a promoter and 5' coding sequence. However, they can be introduced into the expression locus by RecA-dependent recombination, resulting in an altered structural subunit and antigenically variant pili.¹³⁶ Because *N. gonorrhoeae* is naturally transformable, horizontal exchange of species-specific DNA may also give rise to new *pil* sequences.

The African trypanosomes (including *Trypanosoma brucei*) are parasites that cause sleeping sickness in sub-Saharan Africa and account for more than 50,000 deaths per year. These organisms are able to avoid humoral immunity by antigenic variation of a large family of proteins called variable surface glycoproteins (VSGs), which coat the entire surface of the trypanosome. VSGs are highly immunogenic and stimulate antibodies that lead to efficient and rapid clearing of parasites from the bloodstream. However, at any given point in time, the organism is able to express a new VSG, allowing some organisms to escape the antibody response against the previous VSG. Each parasite can express more than 100 different VSGs, with variation in expression occurring spontaneously at a rate of up to 10⁻² per cell per generation. Overall, the genome of *T. brucei* contains more than 1000 *vsg* genes, including so-called expression sites (ESs) located near telomeres on minichromosomes and silent loci in nontelomeric sites on large chromosomes.^{241,310} In general, VSG antigenic variation occurs by two different mechanisms. The first is called *in situ* activation and involves the simultaneous activation of a new ES and inactivation of the old ES, occurring independently of DNA rearrangement. The second involves DNA recombination, either between the expressed *vsg* and another telomeric ES (reciprocal recombination) or between the expressed *vsg* and a silent *vsg* locus (gene conversion).³¹⁰

In the case of *H. influenzae*, lipopolysaccharide (LPS) is likely a key factor in facilitating colonization and is also a major target of the antibody response to infection. Interestingly, *H. influenzae* LPS undergoes phase variation. LPS biosynthesis involves multiple enzymatic steps and a number of genes. Among these genes, *lic1A*, *lic2A*, *lic3A*, *lex-2*, *lgtC*, and an *oafA*-like gene contain long stretches of tandem four-base pair repeats within their 5' coding region. In studies of the *lic* loci, Weiser and coworkers observed that the number of repeats varies spontaneously, generating translational frameshifts with different ATG start codons falling in or out of frame.³²⁴ Such frameshifts result in synthesis of a protein with a different N terminus or eliminate protein production altogether (when no in-frame start codon exists). The mechanism of variation in repeat number is presumed to be slipped-strand mispairing, which occurs during DNA replication and involves a single repeat looping out on either the template or the replicating strand. Changes in *lic2A* and *lic3A* influence glycotransferase activity and alter reactivity with monoclonal antibodies directed against specific LPS oligosaccharide epitopes.¹⁰⁸ The *lic2A* gene product is responsible for the addition of a Gal- α 1,4-Gal moiety, which resembles the globoseries glycolipids and protects *H. influenzae* from antibody-mediated killing, possibly by molecular mimicry.³²⁵ *lgtC* may be involved in formation of a Gal- β 1,4-Glu moiety.¹³² Variation in the *lic1A* gene affects production of a choline kinase responsible for addition of phosphorylcholine to the LPS molecule, a physical change that enhances binding of C-reactive protein and results in susceptibility to serum bactericidal activity.^{187,326,327} Expression of *lex2* results in addition of a tetrasaccharide (Gal- α 1,4-Gal- β 1,4-Glc- β 1,4-Glc) to the proximal heptose in LPS and increases resistance to complement-mediated serum killing.¹⁰⁵ Similarly, expression of the *oafA*-like gene results in LPS O-acetylation, which facilitates resistance to serum killing.⁸⁸

Recent studies of hepatitis A virus (HAV) have identified a novel mechanism by which viruses can evade humoral responses. HAV was long considered to be nonenveloped, a characteristic that seemed well suited to promote fecal-oral transmission. However, elegant centrifugation studies demonstrated that HAV features an envelope as it exits an infected cell.⁸⁰ The enveloped HAV particle (eHAV) is fully infectious. Formation of eHAV requires proteins involved in host cell exosome formation (VPS4B and ALIX), suggesting that HAV has co-opted these pathways to facilitate spread. While temporary, this enveloped form of HAV is fully protected from neutralizing antibodies and likely facilitates cell-to-cell spread in the liver. Following these studies of HAV, additional viruses have been observed to generate a temporary envelope, indicating an established strategy for viruses to evade humoral responses.²⁵³

Encapsulation

Expression of an extracellular capsule represents a common strategy to evade phagocytosis, complement activity, and humoral immunity among pathogenic bacteria, fungi, and parasites. One example is *H. influenzae*, a common cause of childhood bacteremia and meningitis in underdeveloped countries. Among isolates of *H. influenzae*, six structurally and antigenically distinct capsular types are recognized, designated serotypes a to f. Historically, serotype b isolates accounted for more than 95% of all *H. influenzae* invasive disease, reflecting the distinct virulence properties of the type b capsule, which is a polymer of ribose and ribitol-5-phosphate (PRP) and is encoded by the *capb* locus.²¹¹ In animal studies comparing derivatives of *H. influenzae* strain Rd expressing type a, b, c, d, e, or f capsule, the strain expressing the type b capsule was associated with the highest incidence of bacteremia after intranasal inoculation of infant rats. Similarly, this strain was associated with the highest magnitude of bacteremia and incidence of meningitis after intraperitoneal inoculation of experimental rats.³⁵⁴

In considering the mechanism by which the type b capsule promotes intravascular survival and invasive disease, *in vitro* studies using mouse peritoneal macrophages and human peripheral blood monocytes provide some insights. The type b capsule inhibits bacterial binding to macrophages in the absence of complement and a source of C3.²²³ In addition, the type b capsule interferes with ingestion by macrophages when anti-PRP antibody is lacking.^{223,222} Furthermore the type b capsule blocks complement deposition on the bacterial surface and resultant

complement-mediated bacteriolysis. In almost all isolates of *H. influenzae* type b, the *capb* locus is a tandem repeat of 18-kb *capb* gene sequences.²²¹ As a consequence of this arrangement, the *capb* locus serves as a template for further amplification of capsule gene sequences *in vivo*, resulting in increased capsule production. In a study by Corn and colleagues, 23 of 66 minimally passaged invasive isolates had between three and five copies of the 18-kb repeat.⁴⁷ Further analysis demonstrated that amplification of the repeat results in augmented resistance to phagocytosis and complement-mediated bacterial killing.²²¹ The importance of the type b capsule in disease pathogenesis was recognized in vaccine development efforts, and the routine implementation of the Hib polysaccharide-conjugate vaccine in many countries has sharply curtailed the incidence of invasive Hib disease.

Capsule production is also a critical virulence determinant for a number of disease-causing fungi, including the opportunistic pathogen *Cryptococcus neoformans*, which causes infections primarily in HIV-infected and other immunocompromised hosts. *C. neoformans* elaborates a thick polysaccharide capsule that is the basis for the classic "halo" appearance of the organism upon India ink staining of cerebrospinal fluid in patients with cryptococcal meningitis. The capsule comprises a complex polymer with a galactose backbone modified by xylose, mannose, and glucuronic acid. The enzymes responsible for assembly have begun to be identified, suggesting new possible targets for new antifungal development.^{170,257} However, several elements required for capsule biosynthesis remain to be elucidated, and major questions persist regarding the spatial organization of capsule components and the basis for interstrain variation in the chemical structure and antibody reactivity of the galactoxylomannan backbone.⁶⁸

Viral Immune Suppression and Latency

Infection with HCV is a potent inducer of interferon-stimulated gene expression (as with other viruses).³³¹ However, HCV has evolved several mechanisms to evade host innate immune responses. The viral protease NS3-NS4A interferes with nuclear localization of interferon regulatory factor-3 (IRF-3) in response to interferon in HCV-infected hepatocytes.⁸⁹ This disruption of IRF-3 signaling, which prevents cells from activating antiviral genes downstream of IRF-3, results from specific cleavage of the molecule IPS-1.¹⁸¹ Similar observations regarding evasion of innate immunity have been made with the influenzavirus NS1 protein and with West Nile virus and HIV.^{67,69,334}

Among some other viral pathogens, *latency* represents an important mechanism for persistence in the presence of host immunity, especially in the case of viruses belonging to the herpesvirus family. Herpes simplex viruses (HSV types 1 and 2) commonly establish latency after either gingivostomatitis or genital tract infection. After infection of a host cell, HSV replication begins. Eventually cell death occurs, resulting in cell lysis and release of viral particles, which can then infect adjacent cells. This so-called lytic replication cycle is under control of a small number of immediate early (IE) genes, which must be transcribed in moderate amounts to allow expression of the remainder of the viral genome. IE gene expression is activated by VP16, a viral protein that binds to a sequence common to IE gene promoters.²⁵² After lysis of the host cell, new virions enter local nerve termini and travel up the long axon to sensory ganglia, where latency is established within days. In the latent state, viral DNA can be detected in the neuron, but infectious virions cannot be isolated. During latency,²¹⁷ IE genes are repressed and only one fragment of viral DNA is actively transcribed, yielding several latency-associated transcripts (LATs) via alternative splicing.³⁴⁸ No protein product has been definitively attributed to the LAT; instead, recent work has demonstrated HSV-1 production of microRNAs, transcribed from LAT exons, that promote latency by inhibiting transforming growth factor- β signaling, favoring survival of infected cells and regulating the expression of activation-associated viral genes.^{56,109,315} LAT-deficient mutants are still able to establish initial latency, suggesting that IE gene expression may be under multiple controls.³²⁰ The mechanism by which HSV is reactivated is an area of intense study and some controversy. Host cellular mechanisms may provide the inciting signals, and the actions of viral thymidine kinase and the protein ICP0 are required for a return to lytic replication.²¹⁷

CONCLUSION

With the proliferation of molecular techniques in recent years, our understanding of the specific microbial and host factors involved in the pathogenesis of a variety of infectious diseases continues to expand remarkably. As a consequence of this understanding, we have witnessed the development of new vaccines and potential targets for antivirulence therapeutics. In the coming years, it is likely that advances in immunology and microbial pathogenesis will inform novel approaches for treating and preventing human infections. Examples might include inhibitors of type III protein secretion systems,¹⁴⁹ antagonists of periplasmic chaperones, analogs of important host cell receptors, and vaccine adjuvants that direct polarization of T-cell responses. However, given the impressive adaptability of human pathogens, as new therapeutic agents become available, we must remain vigilant for new microbial strategies allowing evasion of our interventions.

Normal and Impaired Immunologic Responses to Infection

2

Michael F. Tosi

This chapter provides an overview of immunologic responses to infection and considers host interactions with different classes of pathogens, normal innate and adaptive immune mechanisms, the developing host responses of neonates, specific primary and secondary immunodeficiencies, and approaches to the evaluation of children suspected of having impaired immunity. Human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) are not considered here because they are addressed fully in Chapter 192B. This chapter is intended to supply a basic understanding of mechanisms involved in normal host responses to infection, an appreciation of the underlying basis and clinical presentation of important immunodeficiencies, and familiarity with general principles of evaluation and management of patients with suspected or documented disorders of immunity.

HOST-PATHOGEN INTERACTIONS

General Features of Host-Pathogen Interactions

Humans are constantly exposed to a daunting number and diversity of microorganisms that can cause infection. Many organisms that usually coexist harmoniously with the human host on the skin or on mucous membranes of the oral cavity, upper airways, or lower gastrointestinal tract may invade and become pathogens only if the balance of the commensal relationship is disrupted. Other organisms are more virulent, and they overtly challenge the host's normal surface barriers and internal defense mechanisms. The human host has evolved a complex array of

protective mechanisms designed to defend itself against these continuous microbial challenges.⁵⁹² To understand the pathogenesis, pathology, and natural history of infectious diseases, familiarity with the features of infectious agents that confer virulence is necessary; these topics are addressed elsewhere in this book. However, it is equally important to understand the elements of the host's response that contribute to containment, elimination, and protection against subsequent infection with these agents. Furthermore, it is important to recognize that host responses to infections also may contribute to the pathophysiology of infectious diseases and may injure the host in other ways.

The characteristic features of specific infectious diseases are determined by the interactions of structural components and released products of microbial pathogens with host tissue, cells, and their products. Virulence tactics commonly employed by organisms include adherence to host cell surfaces, internalization within or invasion of host cells, production of toxins, elaboration of surface barriers such as bacterial polysaccharide capsules, usurpation of host synthetic mechanisms, and direct inhibition of specific defense mechanisms within host cells. The successful evolution of host strategies to protect against microbial attack has resulted in defenses designed to interfere with or to counteract many of these modes of microbial virulence.⁵⁹² In recent decades, some of humanity's oldest microbial adversaries (e.g., smallpox, poliomyelitis, measles) systematically have been, or are being, eradicated with aggressive implementation of immunization programs. In the meantime, previously unrecognized human pathogens such as human immunodeficiency

virus-1 (HIV-1) and Ebola virus have emerged as new adversaries. Moreover, many of our oldest nemeses (e.g., tuberculosis, malaria) continue to elude our efforts to bring them under control, and they remain serious problems worldwide. Continued research at the interface between microbial pathogenesis and immunologic mechanisms is essential for the development of innovative approaches that can support and augment human immune responses to both old and new infectious diseases.

Main Features of Host Responses to Specific Classes of Infectious Agents

Viruses

Viruses are obligate intracellular parasites that consist of genetic material in the form of either DNA or RNA that usually is surrounded by a protein coat and may or may not be bound by a lipid envelope.³⁷² Diseases caused by viruses are remarkably diverse, ranging from mild and merely inconvenient to rapidly fatal, and from acute or brief to chronic or lifelong. However, certain features are common to the pathogenesis of most viral infections. First, viruses must enter host cells to replicate. Viral entry ordinarily is initiated by attachment of a viral surface protein to a specific receptor molecule on the host cell. The specific viral ligands or their corresponding host cell receptors have been identified for some viruses. For example, rhinovirus has evolved a capsid protein that binds to human intercellular adhesion molecule-1 (ICAM-1) on respiratory epithelium²⁴⁵; the envelope glycoproteins of HIV-1 interact with CD4 on T lymphocytes and distinct chemokine receptors on lymphocytes or macrophages^{154,308,589}; and internalization of adenoviruses depends on interaction between a specific peptide sequence in the penton base complex of the viral capsid and α_v integrins on host cell surfaces.⁵⁸⁴ After the virus has entered the host cell, the cellular synthetic machinery is redirected to the synthesis of viral components. As with many native proteins synthesized by the host cell, a portion of newly synthesized viral protein is processed into peptides and presented on the infected cell surface by major histocompatibility complex (MHC) class I molecules (see later discussion). The host mechanisms most important in defense against the majority of viral pathogens include the production of specific neutralizing antibodies against viral surface proteins, the development of specific CD8⁺ cytotoxic T-cell responses that eliminate infected cells, and the production by different immune cells of type 1 interferons (IFNs) that disrupt viral replication.^{38,345,347,476,536} Natural killer (NK) cells appear to mediate the destruction of some virus-infected host cells,^{120,513} and antibody-dependent cellular cytotoxicity (ADCC) may ensue after immunoglobulin (Ig)G antibodies bind to viral antigens on the infected cell, permitting subsequent attachment of either NK cells or cytotoxic T cells via IgG Fc receptors.²⁰⁰ IFNs and other cytokines may enhance NK and ADCC activity, and cytokines such as tumor necrosis factor- α (TNF- α) may exert cytotoxic actions on cells infected with certain viruses.³⁴⁷ Additionally, opsonic complement components bound to viral surfaces can interfere with cell attachment, and the complement-derived membrane attack complex can lyse enveloped viruses.⁶⁰

Bacteria

The human host is colonized with a large variety of bacteria at skin and mucous membrane surfaces.^{108,404} The integrity of these mechanical barriers ordinarily prevents systemic invasion of local commensal bacteria.⁸⁹ The epithelial cells that constitute these barriers, on recognition of an organism as a pathogen, also can release defensins and other microbicidal molecules.²²⁵ In healthy hosts, circulating polymorphonuclear leukocytes (PMNs) help keep the resident flora in check by leaving the bloodstream at the mucosal sites containing the highest bacterial burdens, such as the lower intestine and the gingival crevices of the oral cavity.²⁸ This phenomenon helps account for the increased risk for local and systemic infection caused by oral and intestinal organisms in patients with severe neutropenia, including those who receive prolonged chemotherapy for malignancies, and in patients with phagocyte migration disorders such as leukocyte adhesion deficiency syndromes.²⁸ Important host defenses against most bacteria that invade the human host systemically include the complement system, specific

antibodies that promote both the opsonic and the bacteriolytic functions of complement, and phagocytes.^{1,28,60,293}

Fungi

Host mechanisms critical for defense against fungi are less well understood than those directed at bacteria and viruses, but phagocytes and cell-mediated immunity appear to be most important.^{187,215} The relative importance of these factors appears to depend on the specific organisms involved, as is demonstrated by clinical observations in patients with isolated defects of one or the other. Severe mucosal infections caused by *Candida* spp. are common in patients with acquired or primary cell-mediated immune deficits, such as HIV infection, thymic aplasia (see later discussion), chronic mucocutaneous candidiasis, and some forms of severe combined immunodeficiency, as well as in patients with disorders of leukocyte migration.^{28,187} In contrast to *Candida*, *Aspergillus* infections are not as great a problem for patients with cell-mediated immune defects as they are for patients with defects in phagocytic host defenses, such as neutropenia associated with cancer chemotherapy or stem cell transplantation, or genetic defects in phagocyte killing such as chronic granulomatous disease.^{58,588} Fungi such as *Histoplasma* and *Cryptococcus*, like *Candida*, tend to cause severe infections in patients with defects in cell-mediated immunity, although phagocytes clearly are required for optimal clearance of these organisms.^{170,290,582} The main role of antibodies and complement in protection from fungi probably is to provide opsonic activity to enhance phagocyte function.¹⁷²

Parasites

Parasites such as protozoa and helminths comprise such a widely varying group of pathogenic organisms that it is difficult to generalize about mechanisms of immunity to these organisms as a group. However, the importance of specific host mechanisms in defense against certain parasites may be appreciated by considering the characteristic host responses mobilized by parasitic infection or infestations. Some helminths induce production by host cells of chemokines that recruit eosinophils and stimulate their production. This suggests a likely role for these cells in antiparasitic defenses, and eosinophils have been shown to be important in protection against helminths such as *Strongyloides* and other parasites in this group that can invade tissues. IgE, among the immunoglobulins, appears to play a special role, often in concert with eosinophils, in anthelmintic defenses. IgG also may be important based on the susceptibility of individuals with hypogammaglobulinemia to hyperinfection with *Strongyloides*. Patients with hypogammaglobulinemia also are at risk for chronic or severe infestations with the flagellate intestinal parasite *Giardia lamblia*, suggesting a role for some degree of antibody-mediated protection in normal hosts. Patients with primary or acquired disorders of cell-mediated immunity are prone to development of serious central nervous system and ocular manifestations of infection with the protozoan *Toxoplasma gondii*, an obligate intracellular parasite, as well as hyperinfection with *Strongyloides*.^{299,429}

FEATURES OF NORMAL IMMUNE FUNCTION

The immune system can be viewed as consisting of two broad response categories: innate immunity and adaptive immunity. The former encompasses the more rapid and phylogenetically primitive, nonspecific responses to infection, such as surface defenses, cytokine elaboration, complement activation, and phagocytic responses. The latter involves more slowly developing, persistent, and highly evolved antigen-specific responses, such as cell-mediated immunity and antibody production that exhibit extraordinarily diverse ranges of specificities. The various arms of the immune system engage in a wide range of interactions that may enhance or regulate functions of other components of immunity, adding to the already remarkable complexity of the human immune response, and numerous examples of such interactions will be provided.

Innate Immune Responses

Epithelia, Defensins, and Other Antimicrobial Peptides

The epithelium of skin and mucosal tissue functions as a mechanical barrier to the invasion of microbial pathogens. In recent decades, it has

become clear that epithelial cells also are a major source of antimicrobial peptides that play important roles in local host defense.^{48,224,223,421} Studies of their structure, sources, expression, and actions also have revealed an unexpected range of immunologic activities for these molecules whose functions once were considered mainly antimicrobial in nature.^{2,33}

Epithelial cells of mucous membranes of the airways and intestines, as well as keratinocytes, express the human β -defensins (HBD)-1, HBD-2, HBD-3, and HBD-4. These small cationic peptides are similar to the α -defensins stored in the azurophilic granules of neutrophils, and they display antimicrobial activity against a broad range of bacteria, fungi, chlamydiae, and enveloped viruses.^{48,223,225,421} Their production by epithelial cells may be constitutive, as for HBD-1, or inducible as for HBD-2, HBD-3, and HBD-4. For example, recent evidence indicates that epithelial cells of the airway or intestine can produce HBD-2 in response to activation by bacterial products via the Toll-like receptors TLR2 or TLR4 (see later discussion) on the epithelial cells.^{263,568,574} Stimulation of epithelium by cytokines, including interleukin (IL)-1 or TNF- α also can induce defensin production.^{48,225} Defensins have been reported to exert their antimicrobial action either by the creation of membrane pores or by membrane disruption resulting from electrostatic interaction with the polar head groups of membrane lipids, with more evidence now favoring the latter mechanism.^{48,275} Some microorganisms have evolved mechanisms for evading the action of defensins. For example, bacterial polysaccharide capsules may limit access of microbial peptides to the cell membrane,¹¹² and an exoprotein of *Staphylococcus aureus*, staphylokinase, neutralizes the microbicidal action of neutrophil α -defensins.²⁸⁸

Several immunoregulatory properties of defensins and related peptides, distinct from their antimicrobial actions, have been documented.²²³ Several such peptides have been shown to facilitate post-translational processing of IL-1 β .⁴³⁹ Some of the β defensins have been shown to function as chemoattractants for neutrophils, memory T cells, and immature dendritic cells by binding to the chemokine receptor CCR-6.^{274,403,421} Separately, HBD-2 has been shown to act, via a mechanism that requires TLR4, to activate immature dendritic cells and promote their maturation.^{69,591} The β -defensins also act as chemoattractants for mast cells and can induce mast cell degranulation.⁴⁰² HBD-2 and several other antimicrobial peptides can interfere with binding between bacterial lipopolysaccharide (LPS) and LPS-binding protein (LBP), a process important in activating inflammatory cells via TLR4 (see later discussion).⁴⁹³

Additional antimicrobial peptides of epithelial cells include lysozyme and cathelicidin. Lysozyme, an antimicrobial peptide also found in neutrophil granules, attacks the peptidoglycan cell walls of bacteria and may be released from cells by mechanisms that involve TLR activation.⁴³¹ Cathelicidin, or LL37, like lysozyme, is released from both neutrophils and epithelial cells. It exhibits broad antimicrobial activity and can inhibit lentiviral replication.^{274,527} Cathelicidin also exhibits chemotactic activity for neutrophils, monocytes, and T lymphocytes. This activity is mediated via a formyl peptide receptor-like molecule (FPRL-1), rather than the chemokine receptor (CCR)6 bound by β -defensins.⁵⁹⁰

The release of defensins in response to activation of TLRs and the various actions of these peptides, including their direct antimicrobial activities, their chemoattractant actions for a wide range of immune cells, and their activation of dendritic cell maturation, already suggest a highly complex and regulatory role in the development of host defense and immunity. Genomic evidence for the possible existence of many additional human defensins that have not yet been characterized suggests that current knowledge describes but a small sample of the overall contribution of these peptides to immune responses.^{48,490}

Toll-Like Receptors

Mononuclear phagocytes, including circulating monocytes and tissue macrophages, other phagocytic cells, and many epithelial cells, express a family of receptors that is highly homologous to the *Drosophila* receptor called Toll.^{95,263,370,568,574} These receptors mediate a phylogenetically primitive, nonclonal mechanism of pathogen recognition based on binding, not to specific antigens, but to structurally conserved pathogen-associated molecular patterns.^{8,412,413,595} At least 10 human TLRs with a range of microbial ligands have been identified, such as gram-negative bacterial LPS, bacterial lipoproteins, lipoteichoic acids of gram-positive bacteria, bacterial cell wall peptidoglycans, cell wall components of yeast and mycobacteria, unmethylated CpG dinucleotide motifs in bacterial DNA, some viral particles, and viral RNA.^{8,412,413,595} Gram-positive cell wall components bind mainly to TLR2, and TLR2 also can bind components of herpes simplex virus.^{323,538} TLR2 forms dimers with either TLR1 or TLR6 when bound jointly by their ligands.^{288,342} Gram-negative LPS activates TLR4 indirectly by first binding to LBP, which transfers the LPS to the host accessory protein CD14 at the cell surface. The bound CD14 has no transmembrane domain but associates directly with an extracellular domain of TLR4.^{413,538} MD-2, an additional accessory protein associated with TLR4, also plays a role in binding LPS.⁴³⁴ TLR5 has been identified as the receptor for bacterial flagellin, TLR9 recognizes CpG motifs of bacterial and viral DNA, and TLR3 has been shown to bind synthetic and viral double-stranded RNA.^{56,255,319,323} A listing of known human TLRs with their major ligands and cellular distribution is summarized in Table 2.1.

Signaling by TLRs occurs via a well-described pathway in which receptor binding generates a signal via an adaptor molecule, myeloid differentiation factor 88 (MyD88), that leads to intracellular association with IL-1 receptor-associated kinase (IRAK). In turn, this leads to activation of TNF receptor-associated factor-6 (TRAF-6), which results in nuclear translocation of nuclear factor- κ B (NF- κ B).¹³³ NF- κ B is an important transcription factor that activates the promoters of the genes for a broad range of cytokines and other proinflammatory products, such as TNF- α , IL-1, IL-6, and IL-8. This signaling pathway, based on studies with TLR4, is similar but not identical to the signaling pathways activated by other TLRs.¹³³ The activation of cytokine production by TLRs plays an important role in recruiting other components of innate host defense against bacterial pathogens. However, with large-scale cytokine release, the deleterious effects of sepsis or other forms of the systemic inflammatory response syndrome demonstrate that these

TABLE 2.1 Human Toll-Like Receptors: Their Ligands and Cellular Distribution

TLR	Ligands	Cellular Distribution
TLR1 (+TLR2)	Mycobacterial lipoarabinomannans, bacterial lipoproteins, bacterial lipoteichoic acids, bacterial and fungal β -glucans	Mo, DC, MC, Eos, Bas, AEC
TLR2 (+TLR6)		
TLR3	Viral double-stranded RNA	NK cell
TLR4 (+CD14, MD-2)	Bacterial lipopolysaccharide	M Φ , DC, MC, Eos, AEC
TLR5	Bacterial flagellin	AEC, IEC
TLR7	Viral single-stranded RNA	PDC, NK, Eos, BL
TLR8	Viral single-stranded RNA	NK cell
TLR9	Unmethylated CpG dinucleotides	PDC, Eos, BL, Bas (bacteria, herpesvirus)
TLR10	Unknown ligands	PDC, Eos, BL, Bas

AEC, Airway epithelial cell; Bas, basophil; BL, B lymphocyte; DC, dendritic cell; Eos, eosinophil; IEC, intestinal epithelial cell; M Φ , macrophage; MC, mast cell; Mo, monocyte; NK, natural killer; PDC, plasmacytoid dendritic cell; TLR, Toll-like receptor.

pathways have both beneficial and potentially harmful effects for the host.¹³³ Genetic polymorphisms in TLRs may play a role in determining the balance of these effects in certain individuals responding to the challenge of systemic infection.^{133,352,353}

In addition to their “first responder” roles in generating an inflammatory response to invading pathogens, TLRs may network with other components of innate and adaptive immunity. TLR4 function is suppressed by activation of cells via the chemokine receptor CXCR4.³⁰⁷ Activation of some TLRs also can induce expression of the costimulatory molecule B7 on antigen-presenting cells, which is required for activation of naïve T cells.³⁷⁰

Cytokines

A heterogeneous group of soluble small polypeptide or glycoprotein mediators, often collectively called cytokines, forms part of a complex network that helps regulate immune and inflammatory responses. Included in this group of mediators, whose molecular weights range from about 8 to about 45 kDa, are the ILs, IFNs, growth factors, and chemokines (see separate discussions later). Most cells of the immune system and many other host cell types release cytokines, respond to cytokines via specific cytokine receptors, or both. A list of cytokines and related molecules that play a role in immune function, with selected characteristics, is provided in Table 2.2.^{322,422,443} Excellent general reviews are available,^{321,322,347,422,443} and the use of cytokines as immunomodulating

agents is discussed in Chapter 242. However, two cytokines, IL-1 and TNF- α , are of such fundamental importance in acute host responses to infection that they warrant specific attention here.

IL-1 and TNF- α are small polypeptides, each with a molecular weight of approximately 17 kDa, that exhibit a broad range of effects on immunologic responses, inflammation, metabolism, and hematopoiesis.^{66,422} IL-1 originally was described as “endogenous pyrogen,” referring to its ability to produce fever in experimental animals, and TNF- α , which produces some of the same effects produced by IL-1, was originally named “cachectin” after the wasting syndrome it produced when injected chronically in mice.^{66,422} Many of the physiologic changes associated with gram-negative sepsis can be reproduced by injecting experimental animals with these cytokines, including fever, hypotension, and either neutrophilia or leukopenia.^{66,422} In the development of endotoxic shock resulting from gram-negative sepsis, IL-1 and TNF- α are produced by mononuclear phagocytes in response to activation of TLRs by bacterial LPS. They in turn activate the production of other cytokines and chemokines, lipid mediators such as platelet-activating factor and prostaglandins, and reactive oxygen species. They also induce expression of adhesion molecules of both endothelial cells and leukocytes, stimulating recruitment of leukocytes by inducing release of the chemokine IL-8 and activating neutrophils for phagocytosis, degranulation, and oxidative burst activity.^{66,135} These are all important, usually beneficial host responses to infection. However, at very high levels of activation,

TABLE 2.2 Features of Selected Human Cytokines and Growth Factors

Cytokines and Growth Factors	Main Cellular Sources	Biologic Effects
IL-1	Mo, TL, BL, NK, PMN, others	Broad range of cellular activation in inflammatory and immune responses
IL-2	TL, BL, NK	TL, BL proliferation and activation; enhances TL and NK cytotoxicity
IL-3	TL	General stimulation of hematopoiesis
IL-4	TL, BL, Mast, Mo	TL, BL proliferation; BL isotype switching; stimulates IgE synthesis; enhances MHC class II expression
IL-5	TL	Stimulation of Eos production
IL-6	TL, BL, Mo	Broad inflammatory activity; stimulates BL differentiation and megakaryocyte production
IL-7	Marrow and thymus stromal cells	TL, BL growth and differentiation
IL-8	Mac, Mo, Endo, Epi, PMN, Eos	Activation and chemotaxis of PMN, Eos
IL-9	TL	Mast growth and differentiation; growth of activated TL
IL-10	TL, BL, Mast, Mac	Broad antiinflammatory actions; inhibits synthesis of several other cytokines (TNF, IL-2, IL-3, IFN- γ)
IL-11	Marrow stromal cells	General stimulation of hematopoiesis; BL growth and differentiation
IL-12	BL, Mo	Stimulation of TL growth; induction of IFN- γ production; enhancement of TL and NK cytotoxicity
IL-13	TL	BL proliferation and isotype switching; enhances MHC class II expression; inhibits production of cytokines by Mac
IL-14	TL, malignant BL	Induces BL growth
IL-15	Epi, Endo, Mo, Mac, marrow stromal cells	Enhances NK growth, development, function; enhances TL growth and migration
IL-17	TL	Enhances TL growth; induces Mac cytokine release
IL-18	Kupffer cells, Epi, spleen, Mac	Promotes TL, BL, NK cytokine release; promotes TL, BL cytotoxicity
IL-21	TL	Promotes BL, TL proliferation; NK cytotoxicity
IL-23	Dendritic cells, Mac	Similar to IL-12
IL-25	TL (T _H 2), Mast	TL, Mac T _H 2 cytokine secretion
IL-27	Dendritic cells, Mac	TL responsiveness to IL-12
IFN- α	Mo, TL	Interference with viral replication; increases MHC class I expression
IFN- β	Epi, Fibro	Similar to IFN- α
IFN- γ	TL, NK	Similar to IFN- α , IFN- β ; stimulates Mac inflammatory functions
TNF- α	Mo, Mac, TL, NK	Broad inflammatory effects; fever; cachexia; stimulates catabolism; activation of leukocytes and Endo
GM-CSF	TL, BL, Mo, PMN, Eos, Fibro, Mast, Endo	Growth of PMN, Eos, Mo, and Mac precursors; enhances leukocyte function
G-CSF	Mo, Epi, Fibro	Enhances production and function of granulocytes
M-CSF	Mo, TL, BL, Endo, Fibro	Promotes Mo production; stimulates Mo and Mac function

BL, B lymphocyte; Endo, endothelial cell; Eos, eosinophil; Epi, epithelial cell; Fibro, fibroblast; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; Mac, macrophage; Mast, mast cell; M-CSF, macrophage colony-stimulating factor; MHC, major histocompatibility complex; Mo, monocyte; NK, natural killer cell; PMN, polymorphonuclear leukocyte; TL, T lymphocyte; TNF, tumor necrosis factor.

pathologic effects of this proinflammatory cascade may occur, including vascular instability, decreased myocardial contractility, capillary leak, tissue hypoperfusion, coagulopathy, and multiple organ failure.^{133,569}

For some systemic actions, notably the production of hemodynamic shock, IL-1 and TNF- α are synergistic. Both IL-1 and TNF- α also induce production of IL-6, a somewhat less potent cytokine that exhibits some of the actions of IL-1 and TNF- α .⁴²² The human host produces several soluble antagonists of IL-1 and TNF- α that can modulate their effects, including IL-1 receptor antagonist (IL-1ra), soluble TNF- α receptor (sTNF- α R), and antiinflammatory cytokines, especially IL-10.¹³³

The importance of effects mediated by IL-1 and TNF- α in the pathophysiology of septic shock has prompted much active research aimed at blocking their direct and downstream effects to reduce sepsis morbidity and mortality. To date, despite promise and progress, clinical strategies to interfere with the cytokine-induced cascade that leads to endotoxin shock have continued, overall, to meet with limited success.^{29,43,96,133,212,422,456,562,572}

Chemokines

A specialized group of small cytokine-like polypeptides, chemokines, which all share the feature of being ligands for G-protein-coupled, seven-transmembrane-segment receptors, play a complex role in the immune response as cellular activators that induce directed cell migration mainly of immune and inflammatory cells.^{44,285,304,363,393,472} The chemokines and their receptors have been classified into four families based on the motif displayed by the first two cysteine residues of the respective chemokine peptide sequence. Each of at least 16 CXC chemokines binds to one or more of the CXCRs, CXCR1 to -6. Examples of CXC chemokines include IL-8 and Gro- α . Similarly, at least 28 CC chemokines, such as macrophage inflammatory protein (MIP)-1 α ; regulated and normal T cell expressed and secreted (RANTES); and eotaxin-1, -2, and -3 bind to one or more of the CCRs, CCR1 to -10. The sole CX3C chemokine, fractalkine (neurotaxis), binds to CX3CR1, currently the only receptor in its family. The two XC chemokines, including lymphotaxis, bind to the sole receptor in this family, XCR1. A chemokine nomenclature currently designates each of the chemokines as a numbered ligand for its respective receptor family. In this system, Gro- α is CXC ligand (L)-1 (or CXCL-1), and IL-8 now becomes CXCL-8. Similarly, RANTES becomes CCL-5, fractalkine is CX3CL-1, and lymphotaxis is XCL-1.^{285,472} A review of this nomenclature system tabulates the members of each family with their respective ligands and receptors, as well as with the traditional names in both human and murine systems.²⁸⁵

Virtually every cell type of the immune system expresses receptors for one or more of the chemokines. The cells of virtually any inflamed tissue can release a range of chemokines, and tissues infected with different bacteria or viruses release chemokines that recruit characteristic sets of immune cells.^{235,304} For example, whereas rhinoviruses induce the release of chemokines that result mainly in recruitment of neutrophils (early in the course of infection), Epstein-Barr virus induces a set of chemokines that result in recruitment of B cells, NK cells, and both CD4⁺ and CD8⁺ T cells.²³⁵ It is of interest that almost mutually exclusive sets of chemokines are induced by cytokines associated with T_H1 (IFN- γ) versus T_H2 (IL-4, IL-13) versus T_H17 (IL-17) immune responses (see later discussion), indicating a tight interplay between cytokines and chemokines in determining the type of immune response to specific infectious challenges generated under differing conditions.⁷¹ The specificity of such responses is strongly influenced by the type of chemokines released by specific tissues, the vascular adhesion molecules expressed in those tissues, the chemokine receptors expressed by different leukocyte populations, and the specific adhesion molecules expressed by leukocytes.^{71,235,304}

Modulation of chemokine functions may occur by several mechanisms. Chemokines themselves may be potentiated or inactivated by tissue proteases including tissue peptidases and matrix metalloproteases.³⁶⁹ Heparin sulfate-related proteoglycans on endothelial cell surfaces tether chemokines locally, where they can most efficiently activate circulating leukocytes for adhesion (see later discussion). However, similar proteoglycans free in the extracellular environment may act to bind and sequester chemokines, keeping them from interacting with their cellular receptors.^{136,324} Finally, in addition to the well-described use of chemokine

receptors as coreceptors for viral entry by HIV-1, other viruses, especially members of the herpesvirus family, encode soluble decoy receptors that compete with native host receptors for chemokine binding, thereby disrupting normal host responses.^{136,469}

Natural Killer Cells

NK cells are an important cellular component of innate immunity. They are lymphoid cells found in the peripheral circulation, spleen, and bone marrow that do not express clonally distributed receptors, such as T-cell receptors or surface immunoglobulin, for specific antigens.^{387,388,513} They respond in an antigen-independent manner to aid in the control of malignant tumors and to help contain viral infections, especially those caused by members of the herpesvirus family, before the development of adaptive immune responses.^{513,514} Activated NK cells are an important source of IFN- γ , which limits tumor angiogenesis and promotes the development of specific protective immune responses.^{387,388,513,514}

Regulation of NK cell activity involves a complex balance between activating and inhibitory signals. Several cytokines can activate NK cell proliferation, cytotoxicity, or IFN- γ production, including IL-12, IL-15, IL-18, IL-21, and IFN- $\alpha\beta$.⁵¹⁴ Activating signals via other receptors on NK cells, such as NKG2D, may lead either to cytotoxicity or cytokine production or both, depending on the receptor's association with distinct intracellular adaptor proteins that signal via different kinases.^{514,566} Other molecules on NK cells may act as either costimulatory or adhesion receptors, including CD27, CD28, CD134 (CD40 ligand), and lymphocyte function-associated (LFA)-1 (CD11a/CD18).^{50,514} Additionally, Fc γ RIII (CD16) can contribute to NK cell-mediated antibody-dependent cell cytotoxicity.^{200,387} NK cells are able to distinguish normal cells of self-origin via receptors that recognize specific MHC class I molecules. Activation of such receptors provides an inhibitory signal that protects healthy host cells from NK cell-mediated lysis. Virus-infected cells and malignant cells may express MHC class I molecules at reduced levels, rendering them more susceptible to attack by NK cells.^{120,513} NK cell inhibitory receptors, some of which have been characterized, appear to contain intracytoplasmic tyrosine-based inhibition motifs and antagonize NK cell activation pathways via protein tyrosine phosphatases.^{454,514}

NK cells kill virus-infected or malignant cells by the release of perforin and granzymes from granular storage compartments and by binding of the death receptors Fas and TRAIL-R on target cells via their respective NK cell ligands.^{485,513,514} The mechanisms by which perforin and granzymes mediate target cell death are not fully understood. One or more of the granzymes appear to activate intracellular pathways leading to target cell apoptosis via pathways that involve the mitochondria or caspases or both.^{300,553} Separately, binding of the death receptors also activates caspases, causing target cell apoptosis.^{494,514} NK cells engage in several kinds of interactions with other cells of the immune system, including dendritic cells and other antigen-presenting cells. Dendritic cells can influence the proliferation and activation of NK cells both by release of cytokines, including IL-12, and by cell surface interactions, including CD40/CD40L, LFA-1/ICAM-1, and CD27/CD70.¹⁶⁴ In return, NK cells can provide signals that result in either dendritic cell maturation or apoptosis.^{120,513}

Complement System

The complement system consists of more than 30 different free and membrane-bound activation and regulatory proteins. It has multiple key roles in the clearance of invading microbes, including opsonization, recruitment of phagocytic cells, and lytic destruction of pathogens.^{59,168,169,188,189,208,290,289,292,392}

Approximately 90% of complement proteins are synthesized in the liver, but some components can be produced locally at sites of infection by tissue mononuclear phagocytes and fibroblasts.^{134,438} In healthy persons the majority of complement is found in the circulation. Circulating complement levels vary over time, particularly in the presence of inflammation. The inflammatory response may lead to increases in levels of those complement components such as C3 that are acute-phase reactants or to decreases in individual components and total complement activity as a result of consumption.

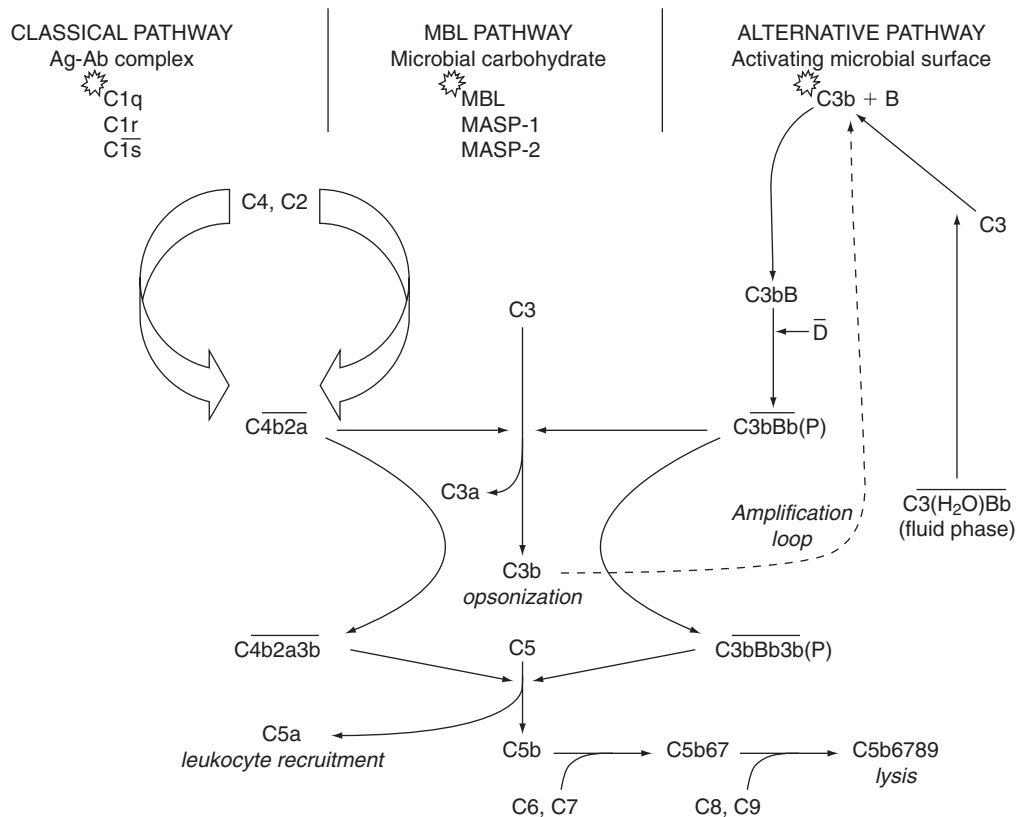

FIG. 2.1 The complement cascade. The initial binding events of the classical, mannan-binding lectin (MBL) and alternative pathways are indicated by a starburst. These pathways intersect at the conversion of C3 to C3b. This is followed by activation of the terminal components, beginning with the binding and cleavage of C5, releasing C5a and leaving bound C5b to initiate assembly of the remaining components to form the membrane attack complex (C5b6789). Enzymatically active proteases of the classical and alternative pathways that cleave and activate subsequent components are, by convention, shown with an *overbar*. The alternative pathway C3 and C5 convertases are shown associated with properdin (P), which increases their stability. B, Complement factor B; D, complement factor D; MASP, MBL-associated serine proteases.

The importance of normal complement component levels and activity in host defense has been well established and is based primarily on the increased susceptibility of patients with specific complement component deficiencies to recurrent or severe bacterial infections.^{166,168,188,289,290} Although the complement response to infection usually is beneficial to the host, it also may be associated with adverse clinical manifestations such as septic shock and acute respiratory distress syndrome.^{158,203,576}

Complement activation. Complement proteins are activated in a specific sequence or “cascade” via one or more of three pathways: the classical pathway, the alternative pathway, and the more recently described MBL pathway, as shown in Fig. 2.1. These pathways converge at C3, and the complement cascade downstream from C3 proceeds identically, irrespective of the pathway by which activation occurs. The C3 convertases, C4b2a for the classical and MBL pathways and C3bBb for the alternative pathway, cleave the C3 molecule at exactly the same location, producing C3b, which binds to the target surface, and C3a, which is released into the fluid phase. Cleavage and activation of C3 lead to a conformational change in C3b that transiently renders its reactive thioester group capable of forming covalent ester or amide bonds with acceptor molecules on the target surface.^{276,331} Surface-bound C3b can act as an opsonin to promote phagocytosis, or it can bind with the classical and alternative pathway C3 convertases to form the C5 convertases C4b2a3b and C3bBb3b, respectively.⁴⁵² C5 convertases bind and then cleave C5, with release of the chemoattractant C5a fragment into the fluid phase. The bound C5b fragment then can initiate formation of the membrane attack complex by the sequential incorporation of the remaining terminal components, C6, C7, C8, and multiple molecules of C9. The membrane attack complex can insert into the outer membrane of target cells, such as erythrocytes or gram-negative bacteria, and cause cell lysis and death.²⁹²

Classical pathway. Ordinarily the classical pathway is activated by IgM or IgG bound to microbial antigenic targets or by other kinds of antigen-antibody complexes.¹⁶⁹ IgM activates complement more efficiently than IgG because only one molecule of polymeric IgM is required in contrast to at least two molecules of IgG.¹⁴¹ Activation typically is initiated when C1q binds directly to an immunoglobulin molecule on the surface of an organism. C1r and C1s are activated and bound to C1q sequentially, forming C1qrs. The enzymatic activity of this complex, which resides in the C1s molecule, can cleave multiple molecules of C4 and C2 into two fragments each. The C4a and C2b fragments are released into the environment, whereas C4b and C2a remain bound to each other on the target surface to form the classical pathway C3 convertase, C4b2a. C4b2a can cleave and activate C3 and localize C3b binding to nearby sites on the target surface. As noted earlier, some C3b binds with C4b2a to form the classical pathway C5 convertase, C4b2a3b.

Alternative pathway. Alternative pathway activation of C3 is the principal means by which a nonimmune host can activate the effector functions of complement until a specific antibody response can be mounted.^{167,205}

A spontaneous low level of hydrolysis of the thioester of C3 in the fluid phase results in an activated form of C3, C3(H₂O). This activated form of C3 can bind factor B, and the latter is then cleaved by factor D to form the fluid phase C3 convertase C3(H₂O)Bb. The constitutive presence of small amounts of this convertase in the fluid phase ensures that a small amount of C3b always is available to bind to microbial surfaces and initiate the alternative pathway.⁴³² The alternative pathway protein factor B can bind to surface-bound C3b, after which factor B undergoes proteolytic cleavage by factor D to release a small soluble fragment, Ba, while the larger fragment, Bb, remains associated with

C3b. C3bBb, the alternative pathway C3 convertase, is analogous to the classical pathway C3 convertase, C4b2a. Properdin stabilizes the C3 convertase C3bBb, permitting more efficient activation of C3 to form more C3b, creating the C3 amplification loop (see Fig. 2.1).^{202,205}

The most important factor in determining whether a specific microbial pathogen will activate the alternative pathway is the biochemical nature of its surface. On surfaces rich in sialic acid, bound C3b is less able to bind factor B because another molecule, factor H, has a strong competitive advantage over factor B under these conditions. When bound by factor H, C3b becomes highly susceptible to further cleavage by factor I (C3b inactivator), resulting in C3bi (or iC3b). Although C3bi is an effective opsonin, it cannot bind factor B. Thus no alternative pathway convertases can be formed, and no amplification loop is established.^{29,325,392} Organisms whose surfaces do not support activation of the alternative pathway, such as K1 *Escherichia coli*, groups A and B streptococci, *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* type b, and some salmonellae are some of the most successful pathogens in infants and young children who lack specific protective antibodies.^{115,292}

Mannan-binding lectin pathway. The most recently described complement activation pathway is the MBL pathway. It is similar to the classical pathway but does not involve antibodies. MBL is a serum protein of the collectin family that has structural and functional similarities to those of C1q. However, it does not require antigen-antibody complexes to initiate its complement-activating function. MBL binds to mannose-containing carbohydrates on microbial surfaces, leading to its association at the microbial surface with activated MBL-associated serine proteases (MASP-1 and -2). These latter proteases have structural and functional similarities to C1r and C1s, respectively, and result in activation of C4, with sequential binding of C4b and C2a and formation of C4b2a, the C3 convertase of the classical pathway. C3 is activated, and the cascade proceeds as described. A more detailed characterization of the MBL pathway and its role in immune responses to infection may be found in an excellent review.⁴⁴⁰

Effector functions of complement in host defense. The principal complement effector functions in host defense include opsonization via bound fragments of C3; phagocyte recruitment, especially via release of C5a; lysis of microorganisms, especially gram-negative bacteria, via the membrane attack complex (C5b–C9); and immune regulation via interactions with host cells involved in adaptive immunity. Complement sometimes may be activated and bound to microbial surfaces but unable to carry out these functions if it is bound to a disadvantageous location; for example, C3b bound to a pneumococcal cell wall beneath a thick polysaccharide capsule or C5b–C9 bound to long lipopolysaccharide molecules distant from the gram-negative bacterial outer membrane.^{93,240,277,292}

Opsonic activity. Complement opsonic activity is essential for effective phagocytic removal of organisms from the circulation by macrophages in the liver and spleen and from other sites by local macrophages and neutrophils.⁷⁸ Opsonins facilitate recognition, binding, ingestion, and killing of microorganisms by phagocytes. Opsonization particularly is important for protection against gram-positive bacteria and fungi because their thick cell walls prevent them from being killed by the membrane attack complex.

The major complement-derived opsonins are the C3 fragments C3b and iC3b. Surface-bound C3b and iC3b permit microbes to be recognized by circulating and tissue phagocytes by interacting with the phagocyte surface complement receptors CR1 (CD35) and CR3 (CD11b/CD18), respectively. These interactions lead to binding, ingestion, and intracellular killing of the organisms.^{117,240,277,276,331}

Antibodies, especially of the IgG class, are important opsonins in their own right, but they also facilitate more rapid complement activation via the classical pathway and more effective localization of C3b binding to the surface of encapsulated organisms, where it is accessible to phagocyte receptors.^{93,277,294}

Inflammation. The cleavage products of several complement proteins contribute to the development of inflammatory responses. C3a stimulates an increase in the number of circulating granulocytes, and C5a serves as a potent stimulus for monocyte, neutrophil, and eosinophil migration toward the source of C5a gradients being produced at infected tissue sites. C5a also upregulates phagocyte expression of CR1 and CR3 and

stimulates these cells to release granule contents that also are important mediators of inflammation and microbicidal activity. C5a-induced neutrophil aggregation and stasis in the pulmonary circulation can be an important feature of the respiratory distress syndrome associated with sepsis.⁵⁷⁶

The anaphylatoxins, C4a, C3a, and especially C5a, induce release of histamine from mast cells and basophils, causing increased vascular dilation and permeability, which, in turn, permit local diffusion of other inflammatory mediators.^{279,576} When large quantities of anaphylatoxins are produced rapidly, they can contribute to septic shock.²⁰³

Microbicidal activity. As noted earlier, C5b and the terminal complement proteins C6, C7, C8, and C9 form the membrane attack complex, which can lyse gram-negative bacteria by penetrating their outer membranes.²⁹² The C5b–C8 complex serves as a polymerization site for several molecules of C9, which increases the efficiency of lysis.^{68,539} As has been noted, the membrane attack complex cannot penetrate the thick cell walls of gram-positive bacteria and fungi and therefore cannot kill these organisms directly. The membrane attack complex can lyse some virus-infected host cells and some enveloped viruses themselves.¹⁴³

Immune regulation. Complement components and fragments can modulate immune responses, both directly by binding to CR1, CR2, and CR3 on the surfaces of T cells, B cells, and other cells involved in antigen recognition and indirectly by stimulating the synthesis and release of cytokines.¹⁹⁵ For example, the C3b cleavage product, C3dg, when covalently bound to antigen, brings the antigen close to B cells by binding to B-cell CR2 (CD21).^{70,84,113} C3 influences antigenic localization within germinal centers, and it is involved in anamnestic responses and isotype switching. Additionally, C1-, C2-, C4-, and C3-deficient animals have decreased antibody responses that can be restored by providing the missing protein,^{70,84,113} and C2 deficiency in humans also has been associated with antibody deficiencies.^{15,113}

Phagocytes

PMNs, the most abundant circulating phagocytes in the human host, will serve as a model for discussing phagocyte functions. These cells constitute a major line of defense against invading bacteria and fungi. The proliferation of myeloid marrow progenitors and their differentiation into mature progeny are regulated by specific growth factors and cytokines.^{45,345,346,547} The normal half-life of circulating PMNs is approximately 8 to 12 hours.^{365,570} In the absence of active infection, most PMNs leave the circulation via the gingival crevices and the lower gastrointestinal tract, where the resident flora stimulate ongoing local extravasation of PMNs, a process that helps maintain the integrity of these tissues.²⁹ In response to invasive bacterial infection, circulating PMNs engage in three major functions: (1) migration to the site of infection, (2) recognition and ingestion of invading microorganisms, and (3) killing and digestion of these organisms.

Phagocyte recruitment to infected sites. Activation of endothelial cells that line the microvessels of acutely infected tissue occurs via locally produced cytokines, eicosanoid compounds, and microbial products.^{110,505}

As a result, the endothelial cells rapidly upregulate their surface expression of P-selectin from preformed intracellular storage pools and, subsequently, of E-selectin by new synthesis.^{344,509} These selectins interact with the fucosylated tetrasaccharide moiety sialyl Lewis X, which is presented on constitutively expressed glycoproteins on PMNs including L-selectin and P-selectin glycoprotein ligand-1 (PSGL-1).^{328,344,598} These early interactions slow the PMNs in this first adhesive phase of leukocyte recruitment, sometimes described as “slow rolling.”^{67,110,505} Within several hours, newly synthesized ICAM-1 is expressed at the endothelial surface.^{110,505,508} The slowly rolling PMNs are activated by transient selectin-mediated interactions and locally produced mediators, especially endothelium-derived chemokines such as IL-8.³⁴³ These chemokines are most effective in PMN activation when they are bound by complex proteoglycans at the endothelial cell surface.^{324,573} The activated PMNs then signal the conformational activation of binding function of their surface β_2 integrins LFA-1 and Mac-1,^{171,563} as well as translocating an additional large quantity of Mac-1 from intracellular storage pools to the cell surface.^{60,80,82} This newly translocated Mac-1 also may undergo conformational activation as the PMN is exposed to increasing

FIG. 2.2 Events during leukocyte (polymorphonuclear leukocytes [PMNs]) recruitment to infected sites. Interactions between microorganisms in infected tissue and host cells and proteins result in elaboration of mediators that diffuse to the local microcirculation and stimulate the endothelial cells. This induces new surface expression of P-selectin and E-selectin, release of interleukin-8 and other chemokines, and new surface expression of intercellular adhesion molecule 1 (ICAM-1). The endothelial selectins bind to constitutively expressed carbohydrate ligands on circulating PMNs and slow the passage of the PMNs through the microvessels. As the PMNs slow further, they become activated by interaction with chemokines bound to complex glycopeptides on the endothelial surface. This activation of PMNs increases their expression and binding activity of the β_2 (CD11/CD18) integrins, Mac-1 and lymphocyte function-associated antigen-1 (LFA-1). Interactions between these integrins and ICAM-1 (and ICAM-2 in the case of LFA-1) lead to tight adhesion and spreading on the endothelial surface. These latter adhesive interactions also are used for migration between endothelial cells and through the subjacent extracellular matrix in response to the gradient of chemoattractants, such as C5a, chemokines, and bacterial peptides, released at the infected site. Homophilic interactions between PECAM-1 on the PMNs and endothelial cells (not diagrammed) also appear to contribute to transendothelial migration. (Courtesy Scott Seo, MD.)

concentrations of mediators.^{171,269} These activated β_2 integrins interact with the endothelial cell ICAM-1 in this second, firm adhesion phase, which is necessary for transendothelial migration of the PMNs.^{60,110,170,343,496,505,508} Other chemoattractants, such as C5a, N-formyl bacterial oligopeptides, and leukotrienes (e.g., LTB₄) that diffuse from the site of infection further activate PMNs and provide a chemotactic gradient for PMN migration into tissue.^{177,232,393} The receptors for these chemoattractants, like the chemokine receptors, are G-protein coupled and have a seven-transmembrane-domain structure.^{232,393} They constitute important sensory mechanisms of the PMNs for activating adhesion, directional orientation, and the contractile protein-dependent lateral movement of adhesion sites in the PMN membrane necessary for cell locomotion.^{24,232,393,531} A scheme for PMN recruitment from the microcirculation into infected tissue is presented in Fig. 2.2. Although the specific stimuli and adhesion molecules may vary, this general scheme applies to the local recruitment of virtually all circulating cells of the immune system.^{71,235,304}

Phagocytosis. After PMNs reach the site of infection, they must recognize and ingest, or phagocytose, the invading bacteria. Opsonization, especially with IgG and fragments of C3, greatly enhances phagocytosis.^{277,293} Although nonopsonic phagocytosis may occur, only opsonin-mediated phagocytosis is considered here.^{483,546} CR1 and CR3 are the main phagocytic receptors for opsonic C3b and iC3b, respectively.^{60–62,204} When PMNs are activated by chemoattractants or other stimuli, CR1 and CR3 are rapidly translocated to the cell surface from intracellular storage compartments, thus increasing surface expression up to 10-fold.^{60,204} Note that CR3 is identical to the adhesion-mediating integrin Mac-1.^{35,60} CR1 and CR3 act synergistically with receptors for the Fc portion of antibodies, especially IgG.^{34,293} Phagocytic cells may express up to three different types of IgG Fc receptors, or FcγRs, all of which can mediate phagocytosis.^{200,556} FcγRI (CD64) is a high-affinity receptor that is expressed mainly on mononuclear phagocytes.⁵⁵⁶ The two FcγRs

ordinarily expressed on circulating PMN are FcγRII (CD32) and FcγRIII (CD16).^{547,556} FcγRII is conventionally anchored in the cell membrane, exhibits polymorphisms that determine preferences for binding of certain IgG subclasses, and can directly activate PMN oxidative burst activity.^{547,556,557} FcγRIII is expressed on PMNs as a glycolipid-anchored protein, although it is anchored conventionally on NK cells and macrophages.^{482,549,556} Many phagocytes also express IgA FcRs, which promote phagocytosis and killing of IgA-opsonized bacteria.^{278,385}

The engagement of phagocyte receptors with microbial opsonins on microbes locally activates cytoskeletal contractile elements, leading to engulfment of the microbe within a sealed phagosome.⁵³⁰ This is followed by fusion of the phagosome with lysosomal compartments containing the phagocyte's array of microbicidal products.

Phagocyte microbicidal mechanisms. Intracellular killing by phagocytes, usually within the fused phagolysosome, involves microbicidal weapons that can be categorized as either oxygen-dependent or oxygen-independent.⁴⁶⁶ The oxygen-dependent microbicidal mechanisms of phagocytes depend on a complex enzyme, reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which catalyzes the conversion of molecular oxygen (O₂) to superoxide anion (O₂^{•−}), the reaction that is deficient in chronic granulomatous disease (see later discussion).^{39,40,129} As the name suggests, the reaction catalyzed by this enzyme requires a supply of NADPH, which is supplied in turn by reactions of enzymes of the hexose monophosphate shunt. The NADPH oxidase is assembled at the plasma or phagolysosomal membrane of activated cells from six known components that include a cytochrome (α- and β-subunits, designated gp91^{phox} and p22^{phox}, respectively) and at least three cytosolic proteins, p40^{phox}, p47^{phox}, and p67^{phox} (“phox” refers to phagocyte oxidase), along with a Rac-1 GTPase, which assemble with the membrane-associated components to form the active enzyme complex (Fig. 2.3).^{40,80,129} Each of the main oxidant products derived from this enzyme's activity exhibits microbicidal activity, including the earliest

FIG. 2.3 The phagocyte reduced nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase enzyme complex and the major reactions in the evolution of oxygen-dependent PMN microbicidal activity. The diagram depicts the six main components of the NADPH oxidase complex: the 91-kDa and 22-kDa subunits of the membrane-bound cytochrome; the 40-kDa, 47-kDa, and 67-kDa cytosolic components; and a Rac-1 signaling molecule. After assembly at the plasma or phagolysosome membrane, the enzyme catalyzes the conversion of molecular oxygen (O_2) to superoxide anion (O_2^-), the initial step in the sequence of production of oxidant antimicrobial products. This reaction requires a supply of NADPH, most of which is derived from activity of enzymes of the hexose monophosphate shunt (not shown). Shown in sequence are subsequent reactions for the spontaneous formation of hydrogen peroxide (H_2O_2), the myeloperoxidase-catalyzed formation of hypochlorite (OCI^-), and formation of chloramines (RNH_2Cl).

products, O_2^- and H_2O_2 , and the more potent downstream products hypochlorite (OCI^-) and chloramines (NH_2Cl , RNH_2Cl), with chloramines being the most stable.^{248,466}

The oxygen-independent microbicidal activity of PMNs resides mainly in a group of proteins and peptides stored within their primary (azurophilic) granules and, to a lesser extent, in their secondary (specific) granules.^{80,81,83,225} Lysozyme is contained in both the primary and the secondary (specific) granules of PMN.⁵²² It cleaves important linkages in the peptidoglycan of bacterial cell walls and is most effective when it can act in concert with the complement MAC.²⁹³ The primary granules contain several cationic proteins with important microbicidal activity. A 59-kDa protein, bactericidal/permeability-increasing protein, is active against only gram-negative bacteria.⁵⁷⁸ Smaller arginine- and cysteine-rich peptides, the α -defensins, similar to the β -defensins of epithelial cells, are active against a range of bacteria, fungi, chlamydiae, and enveloped viruses; other related molecules include cathelicidin and a group of peptides called p15s.^{221,224,225,337,341} Some of these PMN proteins and peptides interact with each other synergistically to enhance overall antimicrobial activity.³⁴⁰

Important Interactions Among Innate Immune Mechanisms

A schematic overview of many of the main features of innate immunity discussed earlier, along with some of their important interactions, is diagrammed in Fig. 2.4. Several levels of interactions are depicted, from initial host-pathogen contact, through a variety of activating signals, to the attack by host effector mechanisms on their respective pathogenic targets.⁵⁴⁵

Adaptive Immune Responses

Adaptive immunity involves the host's antigen-specific responses to infectious challenges that can provide specific protection against subsequent challenges by the same infectious agent. The major steps in the development of adaptive immunity include the processing and presentation of specific antigens to T lymphocytes (T cells) by antigen-presenting cells (APCs); the activation and differentiation of T cells for specific cytotoxic T-cell activity, T-cell cytokine production, and T-cell help in

activating antigen-specific B cells; and the differentiation of activated B cells into plasma cells for the production of specific antibodies. Whereas the innate immune responses described earlier often occur in a matter of minutes to hours and may activate early cellular responses that are essential for the development of adaptive immunity, the full development of most adaptive immune responses requires days to weeks. Once developed, however, the latter often can provide durable protection. A summary of the major events in the adaptive immune response to infection is diagrammed in Fig. 2.5.

Antigen Presentation and Specific Cell-Mediated Immunity

Specific cell-mediated immunity provides T-cell help for antibody production by B cells, cytokine production for the stimulation and regulation of a range of immune responses, and cytotoxic T-cell activity against host cells infected with viruses.^{175,391,436} The development of cell-mediated immunity requires complex interactions between T cells and APCs via several types of surface molecules on the respective cell surfaces. These include binding of an antigen-specific T-cell receptor on the T lymphocyte to a peptide antigen presented on the class I or II MHC by the APCs, with concurrent binding of the class I or class II MHC by CD8 or CD4, respectively,^{144,543} as represented in Fig. 2.6. Other respective pairs of cell-surface molecules that enhance interactions between T cells and APCs include CD40 ligand/CD40, LFA-1/ICAM-1, and CD28/B7. An additional molecule, cytotoxic T lymphocyte antigen-4 (CTLA-4), expressed on activated T cells, also can bind to B7 molecules on APCs to generate a suppressive signal that may terminate T-cell activation.⁵⁴³ The sustained physical interface between T cells and APCs at which these molecular interactions take place has been characterized as the "immunologic synapse."^{32,92,242}

Class I major histocompatibility complex. Virtually all human cells except neurons express class I MHC.^{152,153} The class I MHC molecule presents antigenic peptides to CD8⁺ cytotoxic T lymphocytes.^{67,407} It consists of a heavy chain that contains both the peptide-binding domain and a transmembrane domain and a smaller extracellular subunit,

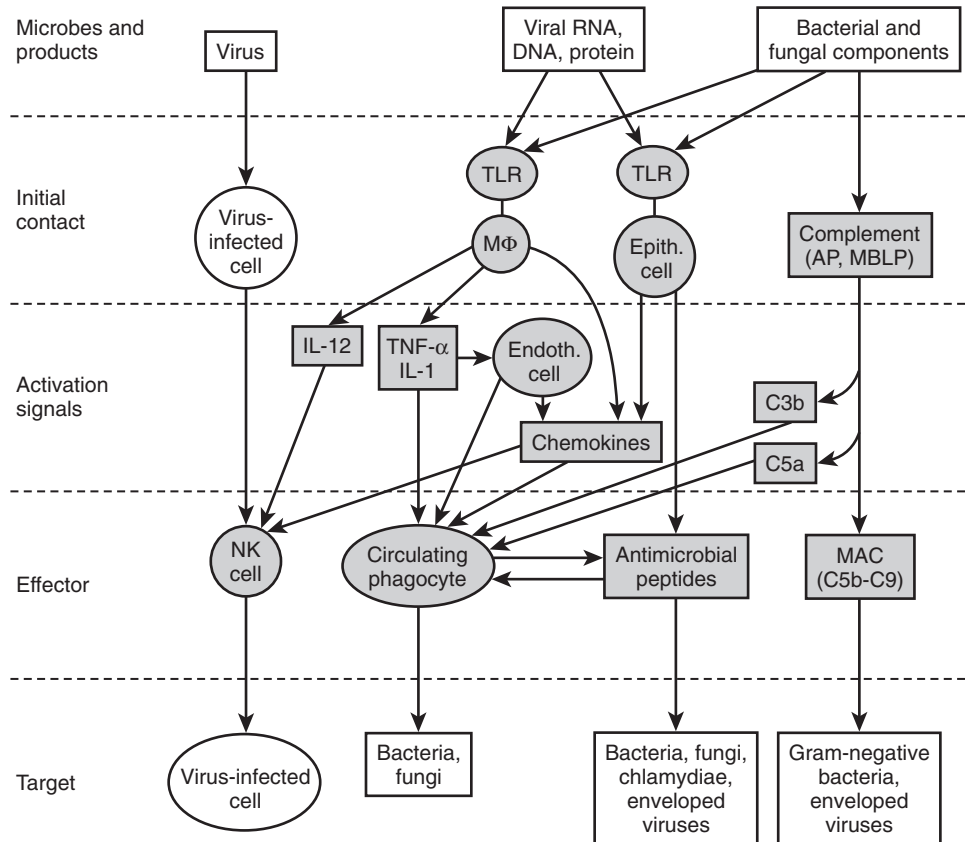

FIG. 2.4 Innate immunity: first contact, intermediate signals, and effector mechanisms. Diagrammed are important host responses to infection that are independent of specific cell-mediated immunity or antibodies. Initial contact between the host and microbes or their products may result in viral infection of cells, activation of Toll-like receptors (TLR) on macrophages (MΦ) and epithelial cells, and activation of the alternative pathway (AP) or mannose-binding lectin pathway (MBLP) of complement. The resulting activation signals, including cytokines (e.g., interleukin [IL]-12, tumor necrosis factor α [TNF- α], IL-1), chemokines, and products of the complement cascade mobilize both cellular (natural killer [NK] cells, phagocytes) and humoral (antimicrobial peptides, membrane attack complex [MAC]) effectors that attack their respective microbial targets. (From Tosi MF. Innate immune responses to infection. *J Allergy Clin Immunol* 2005;116:241–9.)

β_2 -microglobulin.^{73,462} The three major types of class I MHC heavy chains in humans, human leukocyte antigen (HLA)-A, HLA-B, and HLA-C, have at least 22, 31, and 12 different alleles, respectively.⁵⁹⁷ This polymorphism permits a great diversity in the peptide-binding repertoire in individuals and within populations. A restricted degree of MHC genetic polymorphism has been invoked as a possible explanation for the predisposition of certain populations to develop infections.⁷⁴ Class I MHC molecules within the cell ordinarily bind peptides derived from recently synthesized proteins, either of self-origin or of infecting viruses.^{198,199} A portion of newly synthesized proteins is processed into peptides at a cytoplasmic site, the proteasome.²³⁶ These peptides are actively transported into the endoplasmic reticulum, where they are bound in the peptide-binding cleft of MHC class I. Suitable peptides usually are restricted to 8 to 10 amino acids in length, and they must contain certain amino acids at specific “anchor” positions on the peptide to bind.²⁸⁰ Allelic variants of MHC class I may require different amino acids at these anchor positions.²¹⁸ The other amino acids of the peptide constitute the specific antigenic determinant. After trafficking of the MHC-peptide complex to the cell surface, the peptide antigen is recognized and bound by a specific T-cell receptor on CD8⁺ cytotoxic T cells, which concurrently bind the heavy chain of MHC class I via CD8.^{67,218,280,551}

Class II major histocompatibility complex. Mononuclear phagocytes, B lymphocytes, and dendritic cells, including specialized tissue-specific dendritic cells, such as the Langerhans cells of the skin, serve the immune system as “professional” APCs.³⁶⁵ Dendritic cells, the most efficient APCs

for primary activation of naïve T cells, are macrophage-like cells of a distinct lineage that take up and process antigens in tissues and migrate to local lymph nodes or to the spleen, where they are likely to encounter T cells specific for the presented antigens.^{182,183,253,463} A defining feature of these professional APCs is their expression of class II MHC molecules in addition to class I MHC.¹⁵³ Class II MHC molecules consist of an α and a β chain, which together form a peptide-binding cleft.^{94,475} Class II MHC molecules present peptides, 13 to 17 amino acids in length, derived from proteins that are internalized by endocytosis or during phagocytosis of microorganisms.^{251,281,475} The three major types of class II MHC α and β chains are HLA-DR, HLA-DP, and HLA-DQ, each exhibiting a high degree of polymorphism.⁴⁶⁰ MHC class II, bound to a separate smaller molecule known as the “invariant chain,” traffics via the Golgi to endosomal/lysosomal compartments, where it must dissociate from the invariant chain to bind antigenic peptides derived from internalized proteins.^{461,541,542} The class II MHC–peptide complexes then move to the cell surface, where the peptide antigens are bound by specific T-cell receptors of CD4⁺ T cells, which concurrently bind class II MHC via CD4.^{183,351}

Fig. 2.7 depicts the essential features of the conventional antigen presentation pathways that involve class I and class II MHC molecules, as described earlier. Alternative mechanisms have been documented by which class I MHC can present peptides derived from internalized exogenous proteins, and class II MHC may present peptides derived from newly synthesized proteins. The importance of these unconventional pathways of antigen presentation in the immune response is not fully

FIG. 2.5 A simplified scheme of major events in the development of adaptive immune responses. When antigen-presenting cells (APCs) such as dendritic cells (DCs) encounter and internalize microbes or their protein antigens in peripheral tissues, they process the microbial proteins and present the resulting antigenic peptides on either class I or class II MHC molecules. The activated APCs migrate to lymphoid tissue, where they undergo maturation. When mature dendritic cells encounter $CD4^+$ or $CD8^+$ T cells expressing T-cell receptors specific for the peptides presented in the appropriate major histocompatibility complex (MHC) context ($CD4/MHC-II$; $CD8/MHC-I$), binding between the cells occurs via TCR-peptide, MHC- $CD4/8$, and other pairs of accessory molecules, all necessary for stimulating the T cells to become effector cells. Cytotoxic effector $CD8^+$ T cells migrate into the periphery and kill virus-infected cells that present viral peptides via MHC class I. Effector $CD4^+$ cells either migrate to the periphery where they produce cytokines and otherwise regulate immune responses or remain in the lymphoid tissue to provide help to antigen-specific B cells, promoting their proliferation, differentiation, and eventual production by their progeny plasma cells of specific antibodies that can neutralize viruses, prevent microbial attachment, opsonize microorganisms, or activate complement.

FIG. 2.6 Principal cell surface interactions between $CD8$ and $CD4$ T lymphocytes and peptide antigens complexed with major histocompatibility complex (MHC) class I and class II molecules, respectively. $CD3$ (composed of six subunits, ζ , ζ , ϵ , δ , γ , ϵ) is associated closely with the T-cell receptor (TCR), which recognizes a specific peptide presented on MHC molecules. Class I and class II MHC determinants are recognized by $CD8$ and $CD4$, respectively. Additional or accessory interactions are discussed in the text. APC, Antigen-presenting cell. (Modified from Lewis DB, Wilson CB. Developmental immunology and role of host defenses in neonatal susceptibility to infection. In: Remington JS, Klein JO, editors. *Infectious Diseases of the Fetus and Newborn Infant*. 6th ed. Philadelphia: WB Saunders; 2006:92.)

FIG. 2.7 Conventional pathways for peptide antigen presentation by class I and class II major histocompatibility complex (MHC) molecules. In the antigen-presenting cell, a proportion of newly synthesized proteins, whether of viral or host origin, undergo proteolysis into peptides by enzymes that constitute the “proteasome.” The peptides are transported actively into the endoplasmic reticulum (ER), where those with the appropriate length and sequence bind to MHC class I molecules. MHC class II cannot bind peptides in the ER because of interference by the associated “invariant (inv.) chain.” The class I MHC/peptide complex is transported via the Golgi to the cell surface, where it may be recognized by CD8⁺ lymphocytes. Class II MHC molecules pass via the Golgi to a lysosomal compartment, where conditions favor the release of the invariant chain. This permits class II MHC to bind peptides derived from internalized proteins that have entered the lysosomal compartment via fusion of endosomes or phagosomes with the lysosome. The lysosome translocates to the cell surface, where the class II MHC/peptide complex may be recognized by CD4⁺ lymphocytes.

understood, but evidence indicates that such “cross-presentation” may be important for generation of CD8⁺ cytotoxic T-cell response against some viruses or fungi taken up via endocytosis by antigen-presenting cells.^{36,348}

CD1 family of antigen-presenting molecules. The CD1 family includes proteins with significant homology and structural similarity to that of the MHC class I heavy chain but that present lipid and glycolipid antigens. All mammalian species express one or more members of the CD1 family, principally on professional antigen-presenting cells. Four human CD1 proteins, CD1a, CD1b, CD1c, and CD1d, have been identified, each tightly associated with a β_2 -microglobulin subunit. Mycolic acid, lipoarabinomannans, and other related components of mycobacteria are the best-documented foreign antigens presented by CD1 molecules, and both internalized antigens and antigens synthesized within the antigen-presenting cells by ingested mycobacteria may be presented via distinct trafficking patterns of the CD1-antigen complexes. Antigens presented on antigen-presenting cells by CD1 molecules are recognized by a specialized subset of CD1-restricted T cells that usually lack CD4 and CD8; these are known as NK T cells. These cells share characteristics of both NK cells and T cells and exhibit a limited range of T-cell receptor specificity. Greater detail regarding the structure, function, phylogeny, trafficking, expression, and T-cell interactions for members of the CD1 family may be found in a recent review.⁴⁸⁹

Plasmacytoid dendritic cells. A specialized class of dendritic cells known as “plasmacytoid” dendritic cells plays a multifactorial role in both innate and adaptive immune responses. These cells are early responders to viral infections by virtue of their expression of TLR7/9 and their

ability to produce large amounts of type 1 interferons that disrupt viral replication.^{38,536} Additionally they can play an auxiliary role in the adaptive immune response by providing help to conventional dendritic cells during antigen presentation, apparently by helping to sustain IL-12 production by the latter in response to IFN- γ released by interacting T cells.^{38,536}

T Lymphocytes

The development of T lymphocytes, or T cells, begins when prothymocytes leave the marrow and enter the subcapsular region of the thymus.¹⁸¹ By mechanisms that are poorly understood, the thymic environment induces the rearrangement of T-cell receptor V (variable), D (diversity), and J (joining) gene segments with the eventual expression of mature α - β T-cell receptors complexed with CD3. The T cells, now coexpressing CD4 and CD8, migrate to the thymic cortex, where they undergo screening for T-cell receptor specificity both to optimize the repertoire for distinguishing self from nonself and to eliminate T-cell receptor rearrangements that result in undesirably high self-reactivity. Thymocytes that do not pass this dual screening procedure receive signals that induce programmed cell death (apoptosis).^{373,394,567} Only about 5% of the original thymocytes pass this screening, after which they express either CD4 or CD8 but not both.^{373,394,458,567} Mature thymocytes are released into the periphery, where the CD4⁺ cells serve as the main source of IL-2 and provide help for B-cell antibody production, and the CD8⁺ cells engage in specific cytotoxic activity.^{231,391} This discussion of T cells and T-cell receptors specifically relates to T cells that express T-cell receptors composed of α and β chains, or α - β T cells. T

cells of a distinct type, $\gamma\delta$ T cells, are far less numerous in most tissues (intestinal epithelium is a notable exception), exhibit much less T-cell receptor diversity than do $\alpha\beta$ T cells, may not require an intact thymus for development, and play a role in host responses to certain intracellular bacterial pathogens, including *Listeria* and mycobacteria.^{106,254}

Antigen specificity of $\alpha\beta$ T cells resides in their T-cell receptors, which are integral membrane proteins that exhibit structural homology with immunoglobulins. T-cell receptor diversity results from a rearrangement of V, (D), and J segments.²²⁶ There are up to 100 different V segments, one (D) segment, and as many as 100 different J segments in the complete germline configuration of the T-cell receptor genes. Rearrangement of these gene segments into a mature VDJ sequence occurs by the action of a recombinase enzyme complex formed by two proteins, RAG-1 and RAG-2.^{417,488} T-cell receptor diversity is generated by several factors, including the range of possible combinations of V, (D), and J segments; the imprecise action of the recombinase complex; the variability in the number of nucleotides deleted during rearrangement; and the action of another enzyme, terminal deoxynucleotidyl transferase, which appears to add nucleotides at random to extend segments during rearrangement.^{206,504} The actions of Artemis and DNA ligase IV, two enzymes critical for the processing and joining of DNA ends, introduce additional sources of variability.^{99,191,355,585} It has been estimated that as many as 10^{15} different T-cell receptor specificities theoretically could result from the preceding mechanisms.¹⁵⁹

Stimulation of naïve CD4⁺ or CD8⁺ T cells occurs as they circulate through peripheral lymphoid tissue and encounter dendritic cells and other professional APCs. Localized T-cell migration is highly regulated by specific chemokines and adhesive interactions with local endothelium and involves mechanisms similar to those discussed earlier for circulating phagocytes.^{185,320} When T cells engage APCs presenting specific peptide antigens on the appropriate MHC molecules, they are activated via their T-cell receptor and several costimulatory molecules, especially CD28, to produce IL-2 and proliferate and differentiate into effector T cells.^{128,284}

Effector CD4⁺ T cells may be of the T_H1 or T_H2 type, and this type is influenced by several factors, including the specific cytokines elicited by a particular microbial pathogen.³⁹⁵ Naïve T cells activated in the presence of IL-12 and IFN- γ are likely to develop into T_H1 cells, whereas IL-4 and IL-6 tend to drive development in the direction of T_H2 cells.^{390,395,397} Preferential development of T_H1 effector cells leads mainly to macrophage activation and cell-mediated immunity, whereas T_H2 effector cells help drive certain aspects of humoral immunity, including immunoglobulin class switching to IgE in allergic responses.³⁹⁵ Until recently, before the identification of the T_{FH} subset (see later discussion), T_H2 cells were thought to be the principal cell in providing T-cell help for B-cell antibody production.

A third major subset of effector CD4 T cells are T_H17 cells, whose main function appears to involve protection against extracellular bacteria and fungi by stimulating phagocytic cell responses to these pathogens.^{272,349,382} Their development is favored by the presence of IL-6 and TGF- β and by the absence of IL-4 and IL-12. They are distinguished by their ability to produce IL-17 cytokines, which in turn stimulate local tissues to produce chemokines, such as IL-8, that recruit neutrophils and other phagocytic cells to tissue sites.^{272,349,382} Development of T_H17 cells involves production of IL-21, which acts in an autocrine fashion to activate signal transducer and activator of transcription 3 (STAT3), a transcription factor that drives T_H17 cell development.^{272,382}

In contrast to T_H1, T_H2, and T_H17 CD4 T cells, which exert their main effector functions in the periphery, a fourth T-cell subset, T follicular helper cells, or T_{FH} cells, appears to account for most of the CD4 T cells that provide help to B cells in the lymphoid follicles for antibody production.^{306,411} T_{FH} cells are characterized by their location in lymphoid follicles, expression of the CXCR5 chemokine receptor, and their ability to secrete cytokines typical of both T_H1 and T_H2 cells.^{306,411} The developmental origins of these cells in humans and their relationships and interactions with the other T-cell subsets are subjects of current research.

Activation of naïve CD8⁺ T cells by antigen binding, costimulation by accessory binding molecules on antigen-presenting cells, and exposure to cytokines, including IL-2, all lead to clonal proliferation of specific CD8⁺ cells and their differentiation into cytotoxic effector cells. Effector

CD4⁺ T cells bound in common to an APC may play a role in activating naïve CD8⁺ T cells, either by releasing IL-2 or by activating the antigen-presenting cell to provide greater costimulation to the CD8⁺ T cell to make its own IL-2.³¹ Antigenically experienced effector CD8⁺ T cells respond to specific antigenic peptides and costimulatory molecules on infected host cells by activating cytotoxic mechanisms similar to those described earlier for NK cells, including the release of both perforin and granzymes and the generation of receptor-mediated signals for target cell apoptosis.^{345,476,552}

Regulatory T cells. The existence of T suppressor cells was long a subject of debate among immunologists. Within the past decade solid evidence has been developed to support the existence of suppressor T cells, now referred to as regulatory T cells, or T-regs. These cells were discovered when thymectomized mice were noted to develop autoimmune disease. Transfer of T cells that expressed CD25, the α chain of the IL-2 receptor, from normal adult mice to thymectomized mice prevented autoimmune disease. This population of CD4⁺CD25⁺ T-regs can suppress the activity of other immune cells and has been shown to prevent graft-versus-host disease and allograft rejection.⁴⁴⁹ The mechanism of suppression by T-regs is uncertain but may involve direct contact with other cells or secretion of inhibitory cytokines, including IL-10.^{349,484}

These inhibitory cytokines can interfere with T-cell proliferation and inhibit the ability of antigen-presenting dendritic cells to promote T-cell activation.^{349,484} The role of T-regs in immunity to infection is only beginning to be studied, but some current evidence suggests that the action of T-regs with specificity for microbial antigens may suppress protective immune responses to some infections but may also suppress excessive or injurious host responses.⁴⁴⁹

T-cell memory. Some proportion of activated CD4⁺ and CD8⁺ T cells become endowed with the capacity for long-term antigenic memory and can rapidly become effectors on re-exposure to specific antigen. Whether these cells develop directly from naïve T cells or previously have been effector cells, or both, is uncertain, and the mechanisms by which they become memory T cells are poorly understood. Among the features of memory T cells are high-level expression of CD45RO, the ability to suppress activation of naïve T cells of the same specificity, and a homeostatic level of ongoing proliferation in bone marrow and peripheral lymphoid organs.^{296,357,481,599}

T-cell activation by superantigens. The term *superantigen* describes a class of proteins, mainly microbial exotoxins, including most staphylococcal enterotoxins, staphylococcal toxic shock syndrome toxin-1 (TSST-1), and related streptococcal TSST-1-like toxins. These bacterial toxins are potent pyrogens, can induce a potentially lethal toxic shock syndrome, and contain binding domains for both T-cell receptor V regions and MHC class II molecules. Superantigens bypass normal antigen-processing and presentation pathways by binding directly to class II MHC molecules on antigen-presenting cells and to specific variable regions on the β -chain of the T-cell antigen receptor. Through these interactions, superantigens induce a polyclonal activation of T cells at orders of magnitude above levels induced by antigen-specific activation, resulting in massive release of cytokines from T cells and antigen-presenting cells, including TNF- α and TNF- β , IL-1, IL-2, and IFN- γ , that are believed to be responsible for the most severe features of toxic shock syndromes.^{14,450}

B Lymphocytes and Immunoglobulins

B lymphocytes. B lymphocytes (B cells) are the source of humoral immunity in the form of specific immunoglobulin. The earliest recognizable marrow precursors of B cells are pro-B cells whose surfaces bear the pan-B marker CD19. Further differentiation produces pre-B cells and then mature B cells, the latter expressing cell-surface immunoglobulin by which they recognize and bind antigen. B lymphocytes constitute approximately 20% of the lymphocytes in the circulation and peripheral lymphoid tissues, including the lymph nodes, spleen, bone marrow, tonsils, and intestines, and they are identified by the presence of surface immunoglobulin and the pan-B differentiation markers CD19 and CD20.^{109,371}

B-cell activation is initiated by recognition and binding of specific antigens to B-cell surface immunoglobulins. Early activation leads to increased expression of receptors that either bind cytokines (e.g., IL-2, IL-4, and IL-6) or interact with T cells,³²⁷ leading in turn to clonal

proliferation and differentiation into memory B cells and plasma cells in the germinal centers of peripheral lymphoid tissue.³⁰² Some data suggest that B-cell differentiation into memory B cells is favored by exposure to the CD40 ligand on dendritic cells in lymphoid organs, whereas differentiation into plasma cells is favored by exposure to CD23, IL-1 α , IL-6, and IL-10.^{302,540} The plasma cells, later found in bone marrow and liver as well as peripheral lymphoid tissue, are responsible for most free immunoglobulin production.⁵⁴⁰

The B-cell response to protein antigens depends on T-cell help. B cells can process and present antigen to CD4⁺ T_H cells they encounter in the lymph nodes and spleen.^{301,302,540} In the typical sequence of events, B-cell surface immunoglobulin binds to a protein antigen, which is internalized, processed, and presented to the T cell via class II MHC molecules. B cell–mediated activation of T cells during antigen presentation is much more effective for memory T cells, whereas naïve T cells are more likely to be turned off or rendered tolerant.^{197,220} T-cell help is provided for B-cell proliferation and production of antibody against the specific protein antigen. This is mediated by signaling via CD40–ligand interactions with CD40 on the B cell and by the release of cytokines, which also can induce isotype switching.^{163,405,526} Most B-lymphocyte responses to polysaccharide antigens proceed largely without formal T-cell help, although antibody responses to some such antigens may be enhanced in the presence of T cells.³⁸⁴

Immunoglobulin. Immunoglobulin molecules may be bound at the surface of B cells or free in the circulation, mucosal secretions, or tissues. Free immunoglobulins function in host defense against infection by binding to microbial surfaces to prevent microbial attachment, activating complement via the classical pathway, neutralizing viruses and toxins, and participating in the formation of immune complexes.¹²⁸

Ig molecules are composed of two identical heavy and two identical light chains, as diagrammed in Fig. 2.8.^{186,430} The carboxyl terminus of the immunoglobulin molecule is the heavy chain constant, or C_H, region. The amino acid sequence of this region determines the immunoglobulin isotype. The heavy chain is encoded by V, (D), J, and constant (C) regions on chromosome 14.^{63,571} Each immunoglobulin molecule has a pair of either κ or λ light chains, defined by distinct constant regions.

FIG. 2.8 Structure of an immunoglobulin molecule. The schematic structure of immunoglobulin G (IgG) is shown, depicting the variable (V) and constant (C) regions of both the heavy (H) and light (L) chains, the disulfide bonds that link the two heavy chains at the hinge region and the CL region with CH₁, and the antigen-binding sites formed by the complementarity-determining regions of VH and VL.

The variable region of the immunoglobulin molecule contains the antigen-binding site. Like the T-cell receptor, the Fab region consists of two identical heavy and light chain pairs; similarly, broadly diverse antigen specificity results from the variable nature of recombinase-mediated DNA rearrangements of the three hypervariable, or complementarity-determining, regions (CDR1, CDR2, and CDR3) and the four framework regions during B-cell development.^{201,334,359} The imprecision inherent in this rearrangement, involving mechanisms similar to those described for the T-cell receptor, leads to the generation of more than 10¹² potential antigenic specificities. Somatic hypermutation of variable regions after gene rearrangement adds to the repertoire, and further diversity results from differences in approximation of the three CDRs in relation to each other, affecting the three-dimensional structure of the antigen recognition site.^{408,433} Thus unlike most T-cell receptors, which recognize specific peptide sequences, the antigen-binding domain of an immunoglobulin molecule recognizes the three-dimensional structure of its respective antigen.^{43,156}

All immunoglobulin is derived from B cells expressing surface IgM. B cells may change immunoglobulin isotype when they differentiate into plasma cells, which produce only one class or subclass of immunoglobulin each. Isotypes other than IgM are the result of isotype switching by replacing a part of the constant region of the immunoglobulin heavy chain with another isotype-specific segment.^{447,526} As already noted, isotype switching primarily depends on specific B-cell interactions with cytokines and T cells. The variable region remains unchanged during isotype switching; thus there is no change in antigen specificity. However, important features of immunoglobulins, including half-life, localization in tissues, ability to activate complement, and interactions with cellular IgG receptors, are directly determined by isotype.^{91,287,556}

In addition to isotype switching, immunoglobulins undergo the process of “affinity maturation.” As B cells proliferate in lymphoid tissue in response to persistent or repeated antigen exposure and T-cell help, they undergo V-region somatic hypermutation. When this mutation results in a reduced or absent affinity for antigen, B cells are less able to become activated and elicit T-cell help. Such B cells die by apoptosis, removing lower affinity immunoglobulin from the repertoire. Alternatively, B cells that undergo a mutation resulting in increased affinity for antigen are better able to bind antigen, present antigenic peptides to T cells, receive T-cell help, and survive to give rise to plasma cells, which in turn will produce immunoglobulin with higher affinity. This is a process that occurs as a result of booster doses of vaccines or during persistent infections, as with cytomegalovirus, for example.^{26,444}

Immunoglobulin isotypes. IgG accounts for about 80% of circulating immunoglobulin and includes the subclasses IgG1, IgG2, IgG3, and IgG4.⁶⁴ The half-life of IgG ordinarily is about 21 days (7 days for IgG3).²⁸⁷ Initial exposure to most microbial protein antigens first induces IgM and then an IgG response consisting of IgG1 and IgG3. IgG2 and IgG4 usually are produced during the secondary immune response. IgG1 usually is made in response to protein antigens.²⁸⁷ In adults, the main antibody response to polysaccharides is IgG2, whereas in infants IgG1 predominates.^{6,17} The functions of IgG in host defense include blocking microbial attachment, opsonization, complement activation, toxin and virus neutralization, and promoting antibody-dependent cell cytotoxicity. IgG1, IgG2, and IgG3, but not IgG4, can trigger complement activation via the classical pathway by binding to C1q.⁹¹

Free IgM usually exists as an immunoglobulin pentamer that has a molecular weight of approximately 950,000 and is stabilized by a single J chain.^{186,314,374,433} Present mainly in the circulation, its half-life is approximately 8 to 10 days. The IgM response is the earliest of the isotype responses, appearing within the first few days of infection, but it is transient. The formation of an IgM response in the absence of an IgG response to infection is not associated with the formation of memory B cells. The main direct action of IgM in host defense is the activation of complement via the classical pathway.³⁷⁴

IgA exists in monomeric circulating and polymeric secretory forms and has a half-life of about 7 days.²⁸⁷ Both forms are produced mainly by plasma cells that have migrated to mucosal sites. Secretory IgA is made up of two or three IgA molecules joined by a stabilizing J segment

that is secreted by plasma cells and a secretory component produced by mucosal epithelial cells.^{303,314} The secretory component permits delivery of IgA to mucosal surfaces.⁴⁰⁶ There are two subclasses, IgA1 and IgA2, that differ in the composition of their heavy chains. Most IgA in the circulation is IgA1, whereas most IgA in secretions is IgA2. IgA1 may be cleaved at mucosal sites by bacterial proteases.³¹³ IgA neutralizes viruses at mucosal sites, may block bacterial adhesion, and can act directly as an opsonin to promote phagocytosis and via Fc α receptors.^{278,303}

The IgE molecule has a molecular weight of 200,000 and a half-life of only 2.3 days.²⁸⁷ Most IgE is produced by plasma cells in lymphoid tissue near gastrointestinal and respiratory mucosal surfaces and released into the circulation.^{286,534} IgE acts via Fc ϵ receptors to trigger activation and degranulation of mast cells and basophils, leading to immediate hypersensitivity reactions.⁵³⁴ Persons with intestinal metazoan parasites often have elevated serum levels of IgE, and IgE may have a role in protecting against parasitic disease by stimulating mediator release from mast cells that can recruit eosinophils and cause intestinal smooth muscle contraction and expulsion of parasites.⁵³⁴

IgD has a molecular weight of approximately 180,000 and a half-life of 3 days.²⁸⁷ It is expressed along with IgM on surfaces of naïve B cells but is present in normal adult serum and secretions in very low concentrations. Some antigenic specificity for IgD has been demonstrated, and although its function in host defense is unclear, it may serve as a secondary antigen receptor on B cells, where it may regulate the development of B-cell antibody responses.⁷⁶

CLINICAL CONDITIONS ASSOCIATED WITH DEFICIENT HOST RESPONSES TO INFECTION

Immature Host Responses of the Newborn Infant

It is well recognized that newborn infants are much more susceptible to serious infections from many types of organisms than are older children and adults. This predisposition to infection is even more profound in infants born prematurely. The basis for this special vulnerability of the neonate is complex and encompasses all arms of the immune system.^{332,342,583}

Cell-Mediated Immunity

Antigen presentation per se, via the mechanisms discussed earlier, appears to be relatively intact in the newborn infant. Expression of class I and II MHC molecules has been documented in a broad range of fetal tissues by 12 weeks' gestation,^{271,419} and levels of expression are sufficient to mediate normal MHC class II-restricted antigen presentation by neonatal monocytes to maternal or paternal CD4⁺ T cells, as well as to induce vigorous rejection of allogeneic fetal tissue by CD8⁺ cytotoxic T cells.^{258,270}

By about 20 weeks' gestation, the fetal repertoire of diversity of T-cell receptors has developed fully.⁵⁶¹ At the time of birth, although most basic functions of cell-mediated immunity are present, a high proportion of immature T cells are in the peripheral circulation, which can be identified by their coexpression of CD4 and CD8.³⁴² This phenotype typifies type II thymocytes, which usually are not found in the periphery in older persons.

Neonatal T cells appear to be relatively deficient in most of their major functions, including CD8⁺ T cell-mediated cytotoxicity, delayed hypersensitivity, T-cell help for B-cell differentiation, and diminished cytokine production. Lack of prior antigenic exposure largely explains these defects because memory T cells are much more efficient in all of these functions.^{256,342}

B Cells and Antibody

B cells. Pre-B cells are found in the fetal liver and omentum by 8 weeks' gestation and in the fetal bone marrow by 13 weeks' gestation.^{228,342,516} Pre-B cells with surface IgM have been detected as early as 10 weeks' gestation. After 30 weeks' gestation and delivery, pre-B cells are seen only in the bone marrow. Mature B cells are present in the circulation by the eleventh week and have reached adult levels in the bone marrow, blood, and spleen by the twenty-second week of gestation.^{161,228,516}

Fetal B cells express only IgM, whereas most adult B cells express both IgM and IgD. Neonatal B cells may express three immunoglobulin isotypes (e.g., different combinations of IgG, IgA, IgM, and IgD) on their surfaces.^{228,250}

Although germinal centers are not present in lymphoid tissue at birth, they begin to develop in the first few months of life concomitant with the infant's exposure to antigens.⁵⁴⁴ Despite conflicting in vitro data, neonatal T-cell help for B cells probably is comparable to that of adult T cells, as is reflected by the excellent T-dependent antibody response of the newborn to immunization with protein antigens.¹⁶⁵ In contrast to B cells of older individuals, B cells of neonates and young infants cannot respond to pure polysaccharide antigens. The recruitment of T-cell help to enhance this immature response to polysaccharides has been achieved with the advent of protein-polysaccharide conjugate vaccines. Such vaccines elicit help from T cells specific for peptides derived from the protein component as presented by polysaccharide-specific B cells that have internalized the protein-polysaccharide complex, allowing peptide-specific T cells to activate polysaccharide-specific B cells.⁷⁵

Antibody. Maternal IgG accounts for the great majority of the newborn's circulating immunoglobulin because almost none is made by the healthy fetus and IgG is the only isotype of maternal immunoglobulin that crosses the placenta.^{311,362} Maternal transport of IgG can be detected as early as 8 weeks' gestation, and the newborn's IgG level is directly proportional to gestational age, reaching 100 mg/dL by 17 to 20 weeks' gestation and 50% of the maternal level by 30 weeks' gestation (Fig. 2.9).^{47,90,111} Maternal IgG is transported both passively and actively via trophoblast Fc receptors. Trophoblast Fc receptors have higher affinity for IgG1 and IgG3 than for IgG2 and IgG4, and thus more of those subclasses are transported from the mother.³³⁶

The concept of passive transfer of protective IgG is the basis for development of vaccines for maternal immunization before or during pregnancy so that passive transfer of vaccine-induced antibody will result in protection during the neonatal period. Examples of organisms for which such strategies have been investigated include group B streptococcus, *H. influenzae* type b, meningococcus, pneumococcus, rotavirus, and respiratory syncytial virus.^{46,194,282}

By about 2 months of chronologic age, approximately half of the term infant's quantitative IgG is of maternal and half is of infant origin. The physiologic nadir of IgG in all infants is about 3 to 4 months of age and ranges from less than 100 mg/dL in preterm infants with very-low-birth weight to about 400 mg/dL in term infants (see Fig. 2.9).^{47,593} Maternal IgG usually has waned completely by about 12 months of age, at which time infant levels are approximately 60% of adult levels. Production of IgG1 and IgG3 matures more rapidly than that of IgG2 and IgG4, reaching adult levels by approximately 8 years of age, versus 10 and 12 years of age, respectively.⁴¹⁶

Little IgM, IgA, IgE, or IgD normally is produced by the fetus, and none is transported from the mother.^{311,362} The presence of total IgM levels greater than 20 mg/dL at birth suggests an intrauterine infection, and documentation at birth of specific serum IgM or IgA against relevant organisms, such as *T. gondii* and others, would be diagnostic.^{192,398,418} Serum IgA levels at birth in both preterm and term infants usually are less than 5 mg/dL and consist of both IgA1 and IgA2. Secretory IgA is not detectable until after birth but usually is present within the first few weeks of life. IgM and IgA reach approximately 60% and 20% of adult levels by 1 year of age, respectively (see Fig. 2.9). Secretory IgA reaches adult levels by 6 to 8 years of age.³⁴²

It has been documented that the fetus can respond to antigenic stimulation in the form of maternal immunization with tetanus toxoid vaccine and be primed for a secondary antibody response to repeat immunization after birth.^{233,234} The amount of fetal antibody produced in response to intrauterine antigenic stimulation is proportional to gestational age.^{162,528}

Maternal antibody inhibits the infants' ability to respond to live-virus vaccines against certain organisms, such as measles, but it does not prevent them from mounting protective immune responses to most childhood vaccine antigens, such as tetanus, diphtheria, polio, hepatitis B, and protein-conjugated polysaccharide vaccines.¹² In general, neonates have protective responses to T-dependent antigens even though they

FIG. 2.9 Immunoglobulin (IgG, IgM, and IgA) levels in the fetus and infant in the first year of life. The IgG of the fetus and newborn infant solely is of maternal origin. The maternal IgG disappears by 9 months of age, by which time endogenous synthesis of IgG by the infant is well established. The IgM and IgA of the neonate are synthesized entirely endogenously because maternal IgM and IgA do not cross the placenta. (From Braun J, Stiehm ER. The B-lymphocyte system. In: Stiehm ER, editor. *Immunologic Disorders in Infants and Children*. 4th ed. Philadelphia: WB Saunders; 1996:67.)

may produce less antibody to some antigens than do older infants and adults.^{11,155,165,209,506,512}

The newborn infant's response to T-independent antigens, such as polysaccharides, is poor.²³⁷ The antibody response to most such antigens, including the polysaccharide capsules of group B streptococci, pneumococci, and *H. influenzae* type b, is not mature until 18 to 24 months of age.⁵¹⁰ In contrast, in the first few weeks of life, infants mount excellent antibody responses to T-independent polysaccharide antigens that have been rendered T-dependent by covalent conjugation of the polysaccharide to a protein carrier, as noted earlier.⁷⁵

The response of premature infants to most routine childhood vaccines by 2 months of age, including diphtheria, tetanus, pertussis, and oral and inactivated polio, is comparable to that of 2-month-old term infants.^{7,65,116,512} However, premature infants may not respond as well to hepatitis B vaccine for reasons that are unclear.^{137,330}

Complement

Complement proteins do not cross the placenta, but there is evidence for fetal synthesis of complement beginning as early as 5.5 weeks' gestation, and most complement proteins are present by 10 weeks' gestation.^{135,311} Levels of complement activity and of individual complement components vary significantly among infants, but, in general, classical pathway hemolytic activity of term neonates ranges from 60% to 90% of normal adult values.^{187,594} Alternative pathway hemolytic activity is decreased to approximately 50% to 70% of normal adult values at term.^{5,184,409,502} Complement activity usually is lower in premature than term infants.^{409,502}

Hemolytic activity of both the classical and alternative pathways rises rapidly and reaches adult levels by 3 to 6 months of age and by approximately 6 to 18 months of age, respectively. In addition to hemolytic activity, complement-mediated opsonic and bactericidal activity is decreased in newborn sera and generally correlates with C3 and factor B levels.¹⁸⁷ Studies of opsonic and bactericidal activity of newborn sera have been reviewed in detail elsewhere.^{187,289} Levels of individual complement proteins do not always correlate with their functional activity.^{229,277} Zach and Hostetter⁵⁹⁴ reported not only that

total C3 levels in neonates were decreased but also that C3 thioester reactivity was decreased and that it correlated with gestational age.

Phagocytes

The newborn infant exhibits both quantitative and qualitative deficits in phagocytic defenses. Although the number of circulating PMNs usually does not differ greatly from that in older children and adults, under conditions of stress, including systemic infection, the availability of marrow reserves of PMNs is impaired markedly.¹²⁵ Whereas the ratio of marrow neutrophil reserves to circulating cells in older persons is nearly 15:1, in the newborn infant this ratio is more often between 2:1 and 3:1.¹²⁵ Thus, neutropenia is more likely during severe systemic infections in the newborn than in older children and adults.¹²⁵ Distinct from this quantitative deficiency in marrow reserves of PMNs, functional impairments of PMNs also are important in understanding neonatal phagocytic defenses.

The most important and best-documented functional impairments of neonatal PMNs are related to defective adhesion and migration.^{3,4,23–25,27,317,367,375,376} Specific structural, functional, and biochemical abnormalities have been documented, any or all of which may contribute to the overall impairment in adhesion and migration of these cells.²⁶⁷ Impaired adhesion of neonatal PMNs to endothelial cells and other biologic substrates has been linked with deficiencies in the expression or function of the β_2 integrins Mac-1 (CD11b/CD18) and LFA-1 (CD11a/CD18).^{3,26,95,295,367} Perhaps the best documented of these is the diminished level of surface expression of Mac-1 on activated neonatal PMNs, although expression on resting PMNs is similar to that of adults.^{95,295} The total cell content of Mac-1 in PMN at the time of birth is related directly to gestational age, and cell lysates of PMNs from very early premature infants (less than 30 weeks' gestation) have been found to contain less than 20% of the Mac-1 content of an equal number of adult PMNs, increasing to about 60% by term.³⁶⁷ The PMN content of LFA-1, which is normal at term, appears to be reduced in infants born before 35 weeks' gestation.³⁶⁷ In addition to reduced integrin expression, reduced adhesive function of the β_2 integrin molecules themselves at the surface of activated PMN has been documented.²⁶ Several other

defects of neonatal relative to adult PMNs that might influence chemotaxis have been documented. These include defective redistribution of surface adhesion sites,²⁴ impaired uropod formation during stimulated shape change,²⁵ reduced cell deformability,²⁹³ impaired microtubule assembly,²⁵ deficient F-actin polymerization,^{252,479} reduced lactoferrin content and release,²³ reduced ability to effect membrane depolarization and intracellular calcium ion flux,⁴⁷⁸ and impaired uptake of glucose during stimulation by chemoattractants.⁴

Evidence suggests that the number and binding efficiencies of neonatal PMN receptors for chemoattractants are normal.^{24,478,532} In some studies in which assay conditions are designed to expose a potential defect (e.g., limiting concentrations of opsonins and high bacterial inocula), defects in phagocytosis and killing have been demonstrated.^{376,377}

Primary and Heritable Immunologic Deficiencies

The infant or toddler who experiences even six to eight presumed viral upper respiratory tract infections during the course of a winter season, without other complications, ordinarily would not be considered likely to have an immunodeficiency. In contrast, a child who had experienced several episodes of acute otitis media in the previous 4 months, perhaps some accompanied by sinusitis or pneumonia, has displayed reasonable cause to suspect a humoral immunodeficiency.¹⁴⁰ For certain organisms, infection in the healthy host is so decidedly uncommon that even a single episode should prompt a high suspicion of impaired host defenses. *Pneumocystis jiroveci* pneumonia strongly suggests a severe defect of T-cell number or function.¹⁴⁰ Similarly, lymphadenitis or osteomyelitis caused by gram-negative enteric bacilli suggests a defect of phagocytic killing, such as chronic granulomatous disease.^{291,448}

The International Union of Immunological Societies, through an expert committee on primary immunodeficiency diseases, periodically publishes an updated classification of all known primary immunodeficiency disorders based on phenotypic features.⁸⁵ The following discussion of specific immunologic defects, their genetic basis (if known), and their infectious consequences focuses on well-characterized prototypic disorders within most major classes of defects but also will address other related disorders.

Antibody Deficiencies

Humoral immunity is provided by specific antibody and plays an important role in host defense against most pathogens, as is illustrated by the finding that patients with significant antibody deficiencies develop recurrent and sometimes life-threatening infections.^{139,147} They characteristically are prone to recurrent otitis media, sinusitis, pneumonia, and, less often, sepsis and meningitis.

X-linked agammaglobulinemia. X-linked agammaglobulinemia (XLA), first described by Bruton, is a primary immunodeficiency disorder of the B-cell lineage and is the most serious disorder of humoral immunity.^{98,335,468} It is characterized by absent or severely decreased numbers of circulating B lymphocytes and absent or extremely low levels of all classes of circulating immunoglobulins. It is caused by several different mutations in the gene encoding for a B-cell-specific tyrosine kinase, *Btk*, which maps to the long arm of the X chromosome at Xq22.^{554,564} This abnormality in kinase activity results in an arrest in the development of B cells, usually at the pre-B stage, and thus few B cells or their progeny (e.g., plasma cells) are in the circulation or lymphoid tissues.²³⁹

Most persons with XLA develop chronic or recurrent pyogenic bacterial respiratory or gastrointestinal tract infections, and some may have recurrent skin infections.^{98,335} Sepsis and serious focal infections resulting from bacteremia do not occur as frequently but are more common and more severe than in normal hosts. The causative agents of most of these infections are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*, but *Staphylococcus aureus* and *Pseudomonas aeruginosa*, as well as other gram-negative organisms, may be implicated. The most troublesome gastrointestinal tract infections in XLA are caused by *Salmonella*, *Campylobacter*, and chronic infestation with *G. lamblia*. These patients have been found to have unusually severe or chronic enterovirus infections that can be manifested by chronic arthritis, meningoencephalitis, dermatomyositis, hepatitis, or a combination thereof, and several patients with XLA have developed vaccine-related paralytic poliomyelitis after receiving the live oral polio vaccine.³³⁵

The only typical abnormality on physical examination in XLA that is not related directly to infections is the absence or a paucity of normal B-cell-containing lymphoid tissues, such as tonsils, adenoids, and peripheral lymph nodes.

The diagnosis of XLA can be confirmed by studying lymphocyte markers and demonstrating a lack of circulating cells that stain for surface immunoglobulin or with B-cell-specific monoclonal antibodies against CD19, CD20, or both. The number and function of T lymphocytes are normal in XLA. It may be difficult to establish the diagnosis based on immunoglobulin levels in the newborn period because of the presence of maternally derived IgG. However, if suspected, the diagnosis can be made in the newborn period by documenting a paucity of circulating B cells by flow cytometry.

Although individuals with XLA ordinarily are thought of as having a “pure” B-cell disorder, recent evidence reveals that the absence of B cells in XLA is associated with a contracted T-cell receptor repertoire and that mice that lack B cells are unable to prime CD4⁺ T cells for their effector function in clearing *Pneumocystis* infection, findings that are consistent with the important role of B cells in presenting antigen to CD4⁺ T cells.^{420,451}

In contrast to carriers of some other X-linked diseases examined later (see discussion of chronic granulomatous disease), circulating B lymphocytes of XLA carriers express only one population of B cells, those with the normal allele on the X chromosome, presumably because B cells with the mutant allele are at a selective disadvantage and do not develop. Advances in genetic techniques have enabled detection of maternal carriers of XLA.¹³⁹ Prenatal diagnosis can be made by genetic studies of amniotic fluid cells or quantitation of fetal circulating B cells.¹³⁹

The prognosis for patients with XLA has improved markedly with earlier diagnosis, high-dose intravenous immunoglobulin (IVIG) therapy, and aggressive use of antibiotics. Before the availability of IVIG, most patients who survived to the third decade of life had chronic lung disease from recurrent pulmonary infections and hearing loss from recurrent otitis media.³³⁵

IgG subclass deficiency. Persons with IgG subclass deficiencies have levels of one or more IgG subclass that are more than two standard deviations below normal for age, normal to slightly decreased total IgG, normal levels of other immunoglobulin isotypes, and, often, a poor antibody response to certain antigens.*

Patients with IgG subclass deficiency who also have IgM and IgA deficiency may have another immunodeficiency disorder such as common variable immunodeficiency (CVID).

The most common kinds of infections in patients with any clinically significant IgG subclass deficiency include otitis media, sinusitis, and pneumonia. Ordinarily, these patients do not have life-threatening systemic infections.

Deficiency of IgG1 is likely to be associated with subnormal levels of total IgG because this subclass accounts for about 60% of total IgG, and it often is associated with other subclass deficiencies.^{16,17,492,498–500}

IgG2 deficiency usually is associated with normal total serum IgG levels and is more likely to be clinically significant if accompanied by IgG4 or IgA deficiency. Patients with IgG2 deficiency typically have poor antibody responses to polysaccharide antigens but normal responses to protein antigens. Like most patients with deficiencies of humoral immunity, their infections primarily are due to encapsulated bacteria and are localized to the respiratory tract.^{498,500}

IgG3 deficiency has been associated with low total levels of serum IgG and recurrent respiratory infections, which also may lead to chronic pulmonary disease.⁴¹⁵

IgG4 deficiency is difficult to diagnose because many normal persons have low serum levels of IgG4, and most normal infants have no detectable IgG4.⁴¹⁶ IgG4 deficiency appears to be of clinical significance, however, if it is associated with IgG2 and IgA deficiency.

The treatment for children with IgG subclass deficiency typically is individualized according to the frequency and severity of symptoms. Noninvasive infections usually can be treated successfully with appropriate antibiotics. Patients with more severe presentations may benefit from

*References 260–262, 386, 416, 425, 426, 491, 492, 497–501.

regular IVIG therapy, but those who also are completely IgA-deficient should be treated only with IgA-depleted IVIG preparations.

IgA deficiency. IgA deficiency is the most common immunodeficiency, occurring as frequently as 1/400. This disorder appears to occur sporadically, but familial cases have been described.^{22,147} Most of the functions of serum IgA can be performed by IgG and IgM.^{147,416} Thus, although deficiencies of secretory IgA may lead to recurrent respiratory or gastrointestinal tract infections, deficiency of serum IgA alone usually is not associated with increased susceptibility to systemic infections.²² IgA deficiency has been associated with many other conditions, including recurrent infections, IgG2 deficiency, autoimmune disorders, and malignancy.²¹ Recurrent infections are most likely to occur in the subset of IgA-deficient patients who also have IgG2 deficiency.^{147,425} The infections usually are relatively mild and involve the upper respiratory and gastrointestinal tracts. Chronic gastrointestinal tract disease in these patients can be caused by *G. lamblia* infestations, nodular lymphoid hyperplasia, lactose intolerance, malabsorption, or inflammatory bowel disease. Other autoimmune diseases associated with IgA deficiency include rheumatoid arthritis, systemic lupus erythematosus, thyroiditis, myasthenia gravis, and vitiligo.¹⁴⁷ About 20% of IgA-deficient patients have allergy, and many have elevated levels of IgE.¹⁴⁷ Food allergy is common and may be the result of abnormal processing of antigen at mucosal surfaces.

Rare patients with serum IgA levels less than 5 mg/dL who receive transfusions may make antibody against donor IgA and have severe reactions when transfused again. IVIG reactions also may occur because IVIG preparations contain varying amounts of IgA. IgA-depleted preparations are available and usually are well tolerated.¹⁵⁰

Transient hypogammaglobulinemia of infancy. The syndrome of transient hypogammaglobulinemia of infancy can be differentiated from the physiologic hypogammaglobulinemia in infants because immunoglobulin levels of normal infants begin to rise by about 6 months of age, whereas those of infants with transient hypogammaglobulinemia of infancy do not begin to increase until between 18 and 36 months of age.⁴¹⁶ Infants suspected of having this syndrome should be evaluated for XLA and CVID (see later discussion) and followed closely until their immunoglobulin levels normalize for age.

Antibody deficiency with normal or elevated levels of immunoglobulins. Some persons with normal levels of all circulating immunoglobulin isotypes are at increased risk for infections similar to those seen in specific deficiencies of immunoglobulin levels described earlier.^{16,18,416} As in other forms of humoral immunodeficiency, the most common infections in these patients are recurrent bacterial respiratory tract infections, although a few patients have developed pneumococcal sepsis.¹⁸ Such persons can be identified by their inability to make antibody in response to stimulation with specific antigens. A good way to test for this disorder is to immunize with protein antigens, such as tetanus and diphtheria toxoids, and with polysaccharide antigens, such as pneumococcal and *H. influenzae* type b capsular polysaccharide vaccines. Patients who can respond to protein but not to polysaccharide antigens usually will respond to protein-polysaccharide conjugates. Treatment with IVIG may help prevent recurrent infections in these patients, although their normal overall levels of immunoglobulin can pose difficulties in determining the appropriate doses of IVIG and intervals between infusions.

Defects of Cell-Mediated Immunity: DiGeorge Syndrome

The prototypic pure T-cell defect, DiGeorge syndrome, is characterized clinically by congenital heart disease (usually involving the aortic arch), hypocalcemic tetany, unusual facial features, and recurrent infections.¹⁷³ The classical, or complete, form of this disorder has absence or hypoplasia of the thymus and parathyroid glands, cardiac or aortic arch deformities, and a stereotypical constellation of abnormal facial features, most notably micrognathia and hypertelorism, all associated with malformation of the 4th and 5th branchial arches during embryogenesis.^{173,318,350,537} Although the condition usually is considered to be associated with immunodeficiency because of the thymic hypoplasia, only about 25% of patients actually exhibit an immunologic defect.⁵⁵ The term *partial DiGeorge syndrome* sometimes has been used to describe patients with the typical constellation of anatomic findings but without

immunodeficiency or similar patients with mild immunologic impairment.²⁷³ Some sources designate this disorder as an “anomaly” or “sequence” rather than a syndrome because of confusion about its relationship to 22q11 deletion syndrome (del22q11) or the more recently defined microdeletion, del22p11.2, a deletion also associated with velocardiofacial syndrome.⁹⁷ Robin and Shprintzen⁴⁵⁹ hold that the findings in DiGeorge sequence, although often associated with del22q11.2, are etiologically heterogeneous and have been associated with other chromosomal deletions such as del10p and del17p or del10q13. Moreover, some individuals with del22p11.2 exhibit abnormalities quite distinct from those of the DiGeorge sequence.^{243,244,273,326,437,459} One candidate gene, *TBX1*, encoding a T-box transcription factor and located in 22q.11.2, has been a recent focus of research into the underlying genetic defect in DiGeorge syndrome. Although mice with mutations in *TBX1* exhibit some features consistent with DiGeorge syndrome, data remain insufficient to confirm the precise role of *TBX1* in human patients with this disorder.²⁴⁹

Because of the serious nature of the cardiovascular defect, many patients with DiGeorge syndrome in earlier decades have not survived long enough for the immune defect to become a clinical problem.²⁷³ However, with improvements in surgical treatment of the heart defects, more of these infants now survive long enough to display manifestations of the immunodeficiency that results in an increased frequency or severity of viral and fungal infections, as well as *Pneumocystis* pneumonia. In such patients, management often has included prophylaxis against *Pneumocystis*, avoidance of live virus vaccines, and, because antibody production is poor as a result of lack of T-cell help, periodic IVIG infusions.²⁷³ HLA-matched bone marrow transplantation has been successful in some cases.^{83,238,273} Earlier work with transplantation of fetal or postnatal thymic tissue provided some long-term success in correcting the immunologic defect.^{238,273} Recently, a highly promising large series of cases of transplantation with postnatal cultured thymic tissue in patients with complete DiGeorge syndrome yielded immune reconstitution with 73% survival at 2 years.³⁶¹

Combined Defects of Cellular and Humoral Immunity

Severe combined immunodeficiency disease. Severe combined immunodeficiency (SCID) describes a heterogeneous group of heritable immunodeficiencies that involve serious impairments of both cellular and humoral immunity, thus leading to recurrent severe infections by a wide range of viral, bacterial, and fungal organisms. SCID has multiple forms, which have been reviewed in greater detail elsewhere.^{102,103,123} At this writing, at least 10 genes have been identified with abnormalities known to result in SCID. X-linked SCID, the most common form, is due to a mutation in the common γ chain of the receptor for IL-2 and several other cytokines (γ_c).^{103,339} The other known forms of SCID are either known or presumed to be autosomal recessive. These include a deficiency of adenosine deaminase, a purine salvage pathway enzyme; a deficiency in Janus kinase 3 (Jak3), a cytokine receptor signaling molecule; and a defect in the α chain of the IL-7 receptor, IL-7R α .^{103,297,555} Mutation of one of at least six different genes whose products play a role in T-cell receptor or immunoglobulin gene recombination or T-cell receptor signaling, including RAG1, RAG2, Artemis, DNA ligase IV, CD3- δ , and CD3- ϵ , also results in SCID.^{103,123,191,210,297,356,457} Additionally, SCID is caused by a mutation in CD45, a phosphatase that regulates signaling thresholds in immune cells.²⁹⁷ Flow cytometry analysis of lymphocyte markers reveals very low to absent B- and T-cell numbers in patients with most forms of SCID.

Long-term management of patients with SCID involves modalities employed in both B- and T-cell disorders, including prophylaxis against *P. jiroveci* pneumonia, avoidance of live viral vaccines, and immunoglobulin replacement therapy.¹⁰³ Bone marrow transplantation from HLA-matched siblings has corrected the defect successfully in some cases and is considered the current treatment of choice.¹⁰¹ Adenosine deaminase deficiency is of historical interest in that it is the first heritable disorder for which gene therapy was attempted, although early success was limited.¹⁰¹ Approaches using retroviral-based gene therapy for X-linked SCID initially appeared to be successful. However, at least three patients developed lymphoproliferative disorders similar to lymphocytic leukemia, with malignant cells demonstrating insertion

of the vector into the promoter or first intron of a proto-oncogene, *LMO2*.^{79,102,118,211,446}

Because the earliest possible treatment with stem cell transplantation often is the key to meaningful survival in patients with SCID, newborn screening programs for SCID based on assays of bloodspots have been introduced in several states and in some countries. These assays are based on quantitation of T-cell receptor excision circles—circular fragments of DNA that are a by-product of T-cell receptor rearrangement during fetal development.^{46,121,445}

Common variable immunodeficiency. CVID is a heterogeneous group of combined immunodeficiencies that differ from most other primary immunodeficiencies in that they often present in the second or third decade of life, although they may present at any age.^{146,148} Patients with CVID characteristically have normal or only modestly decreased numbers of circulating B cells; low, but not absent, levels of IgG, IgM, and IgA; poor responsiveness to antigens; and abnormal T-lymphocyte function.¹⁴⁹

Although both T- and B-cell abnormalities often can be demonstrated, the clinical presentation usually is most like that in patients with humoral or B-cell defects (i.e., recurrent bacterial otitis media and sinopulmonary infections).^{146,259,468} Occasionally, these patients also have infections with organisms more common in persons with T-lymphocyte abnormalities, such as *Pneumocystis*, recurrent herpes simplex virus, and herpes zoster virus infections. Chronic gastrointestinal problems may be due to *G. lamblia* or other intestinal pathogens. CVID patients are prone to nodular lymphoid hyperplasia, autoimmune diseases, and malignancies.

Several gene mutations have been found in patients with CVID. These include the genes encoding for CD19, transmembrane activator and CAML interactor (TACI), receptor for B-cell activating factor of the TNF receptor family (BAFF-R), and inducible costimulatory molecule (ICOS).^{114,487,596}

Patients with CVID usually can benefit from therapy with IVIG, which reduces the incidence of acute infections. However, most patients with CVID, even some of those who undergo long-term treatment with IVIG, develop chronic sinopulmonary disease.^{148,424}

Hyper-immunoglobulin M syndrome. Immunoglobulin deficiency with increased IgM is characterized by low levels of IgG, IgA, and IgE but normal to increased levels of IgM in the circulation and normal numbers of circulating B cells.^{12,37,157} The disorder is caused by an intrinsic T-cell abnormality that impairs class switching from IgM to other isotypes. The basis for the various genetic forms of this defect is in one of several possible defects that involve interactions between CD40 on B cells and CD40 ligand (CD40L) on T cells. B cells from patients with the hyper-IgM syndrome only make IgM antibody, and their B cells only express surface IgM and IgD. The originally described and most common form of the defect is X-linked recessive and results from a mutation in the gene encoding CD40L, a protein expressed transiently on activated T cells.^{12,37,157} More recently described autosomal recessive forms of this disorder involve mutations either in CD40 itself^{157,207} or in a CD40-activated RNA editing enzyme, activation-induced cytidine deaminase.⁴⁵⁵ Other cells express surface CD40, thus neutropenia and the increased incidence of infections caused by *Pneumocystis* and of malignancies in patients with hyper-IgM syndrome also may be the result of impaired cell interactions via CD40.

Clinically, hyper-IgM syndrome is manifested by recurrent bacterial infections, especially of the respiratory tract.¹⁵⁷ Such persons are susceptible to the same kinds of recurrent pyogenic infections associated with other immunoglobulin deficiencies, as well as to infections with organisms more commonly encountered in patients with T-cell defects (e.g., *P. jiroveci*).⁴⁹ Some patients with this syndrome have recurrent diarrhea as a result of *G. lamblia* and *Cryptosporidium* infection that is severe enough to require parenteral nutrition. About half of patients have persistent or recurrent neutropenia. Those with autoantibodies may have thrombocytopenia, hemolytic anemia, nephritis, hypothyroidism, or arthritis.

The diagnosis of X-linked hyper-IgM syndrome may be established by using immunofluorescence to document absent expression of CD40L on activated T cells, absent CD40 expression on B cells, or demonstrating a mutation in one of the genes encoding CD40, CD40L, or the enzyme activation-induced cytidine deaminase.

Treatment of patients with the hyper-IgM syndrome with IVIG usually results in significant clinical benefit.⁴⁹

Wiskott-Aldrich syndrome. Wiskott-Aldrich syndrome is a rare X-linked disorder characterized by thrombocytopenia, small platelets, eczema, recurrent infections, autoimmune disease, and hematologic malignancy. Although both T- and B-cell compartments are affected, it presents phenotypically more like a B-cell or humoral deficiency, with recurrent otitis media, sinusitis, and pneumonia. The defect involves a mutation in the gene encoding a signaling molecule, Wiskott-Aldrich syndrome protein, which regulates “immune synapse” formation and IL-2 production.^{414,415}

Ataxia-telangiectasia. Ataxia-telangiectasia is a rare autosomal recessive disorder characterized by progressive cerebellar dysfunction with ataxia, oculocutaneous telangiectasias, recurrent bacterial respiratory infections such as those seen in humoral deficiencies, and a predilection to hematologic malignancy and breast cancer. Serum immunoglobulins often are low, as are lymphocyte counts. The disorder is due to a mutation in the *ATM* gene, located on chromosome 11. This gene encodes a serine-threonine kinase that is important in cell cycle regulation and double-stranded DNA repair, and it influences expression of *BRCA1* genes associated with breast cancer. The risk for breast cancer in patients with ataxia-telangiectasia is increased 15- to 20-fold over that in the general population. Heterozygotes for missense mutations of the *ATM* gene can be affected because copies of the abnormal protein can interfere with function of the wild-type protein.^{368,410}

Defects of the Interferon-Gamma (IFN- γ) and Interleukin-12 (IL-12) Pathways

Macrophages infected by intracellular pathogens, especially *Mycobacterium* or *Salmonella* spp., are stimulated via a TLR4-dependent mechanism to release IL-12, along with IL-18, IL-23, and IL-27. These cytokines stimulate T and NK cells to produce IFN- γ via interactions with cellular receptors for the aforementioned cytokines. The released IFN- γ , in turn, further stimulates the macrophage to release more IL-12 and to activate killing. The mechanism by which this intracellular killing occurs is unknown. This cycle of mutual activation is essential for normal defense against mycobacterial pathogens, and some genetic defects of these cytokines, their cellular receptors, or related molecules critical for receptor-mediated signaling have been associated with increased susceptibility to mycobacterial infections. Deficiencies in this system have resulted from mutations in either of the two receptors for IFN- γ , IFN- γ R1 and IFN- γ R2, as well as mutations in STAT1, a molecule critical for transducing signals from both IFN- γ receptors. Mutations also have been described in the 40-kDa subunit of IL-12, IL-12p40, and the IL-12 receptor, IL-12R β 1. These disorders are rather uncommon, all involving fewer than 100 known patients.^{423,470}

Mutation of either of the IFN- γ Rs is associated with increased risk for mycobacterial infections. Deficiencies of IFN- γ R1 may be either autosomal recessive or dominant and either complete or partial. Most recessive defects are complete and result in absent IFN- γ responsiveness. Dominant IFN- γ R1 deficiency results from heterozygous truncations of the cytoplasmic domain of the receptor with excessive accumulation of nonfunctional receptors at the cell surface. Patients with the recessive complete form of this deficiency have a much more severe clinical phenotype than those with the dominant partial form, although the latter have a fivefold greater frequency of nontuberculous mycobacterial osteomyelitis. Defects in IFN- γ R2, much less common, also may be recessive or dominant in inheritance and either complete or partial. Rare deficiencies in the receptor signaling molecule STAT1 have led to increased mycobacterial infections in a partial deficiency or, in two patients with a recessive complete form, to postvaccination disseminated bacille Calmette-Guérin (BCG) disease followed later by death from severe viral infections. The latter probably relates to the additional role of STAT1 in development of IFN- α/β -mediated antiviral activity.⁴⁷⁰

Deficiencies of IL-12p40 or its receptor IL-12R β 1 are associated with disseminated nontuberculous mycobacterial infections, tuberculosis, and *Salmonella* infections. The receptor deficiency results in unresponsiveness to IL-12. This defect is apparently autosomal recessive with variable clinical penetrance. Deficiency of IL-12p40 also is variable in its clinical phenotype and has resulted in deaths from severe mycobacterial infections.^{427,470,525}

The approach to specific diagnosis of defects of the IFN- γ pathway has been well systematized, but such studies should be undertaken only in a highly specialized reference laboratory.⁴⁷⁰

Complement Deficiencies

Approximately 0.03% of the general population have complement deficiencies resulting from acquired or congenital abnormalities of single or multiple complement components or regulatory proteins. Excellent reviews of complement deficiencies are available elsewhere.^{166,167,169,176,265,289,471,580}

Congenital or hereditary deficiencies of complement more often are manifested by abnormality or complete absence of a single complement protein, and most of these have been well documented to predispose to potentially life-threatening infections. Most primary complement abnormalities (C1q dysfunction and C1rs, C4, C2, C3, C5, C6, C7, C8, and C9 deficiencies) are inherited as autosomal codominant traits.¹⁶⁶

Patients with homozygous or heterozygous deficiency of the early classical pathway proteins C1, C2, and C4 are more prone to develop autoimmune disease than difficulty with infections. However, approximately 20% of patients with homozygous deficiency of early components have problems with recurrent or severe infections that are similar to those seen in C3 deficiency.^{166,208,471} Their predilection for autoimmune disease probably is due, at least in part, to abnormal solubilization and removal of immune complexes. C2 deficiency has been associated with antibody deficiencies in individuals with recurrent infections.^{15,113}

Deficiencies of alternative pathway proteins predispose to serious, often fatal, infections because of the lack of ability to respond promptly to organisms not previously encountered.¹⁶⁷ Properdin deficiency, the only X-linked complement deficiency, has been associated with fulminant, usually fatal, meningococcal infection.¹⁶⁷ Factor D deficiency is rare and appears to predispose to recurrent neisserial infection.³⁰⁹

Mutations or variants in the gene for MBL, the initiator of the MBL pathway (see earlier discussion), have been associated with an increased risk for recurrent infections.^{176,265} In particular, homozygosity for such mutations or variants was found to be associated with an increased risk for systemic meningococcal disease.²¹⁴

Because all three complement activation pathways converge at the activation of C3, patients who are deficient in C3 are unable to mobilize any of the three main effector functions of complement in host defense—opsonization, phagocyte recruitment, or bacteriolysis. Thus it is not surprising that the most serious complement deficiency state is the rare total absence of C3.^{166,208,471} Patients with deficiencies or mutations of factors H and I have low but detectable levels of C3 because absence of either of these regulatory factors allows continuous activation of the alternative pathway and uncontrolled C3 consumption. Patients with C3 deficiency caused by any of these mechanisms have increased susceptibility to infections caused by encapsulated bacteria such as *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b. Most of these infections involve the respiratory tract (otitis, sinusitis, bronchitis, and pneumonia), but C3-deficient patients also are predisposed to sepsis and meningitis.^{166,208,471} In addition, some C3-deficient persons develop autoimmune diseases.^{166,208,471}

Deficiencies of terminal complement proteins C5, C6, C7, and C8 greatly increase the risk for developing systemic infections with *N. meningitidis* or *Neisseria gonorrhoeae*.⁷² C9 deficiency increases the risk for infection to a lesser degree than do deficiencies of other terminal components. In one study, the risk for meningococcal disease was increased 5000-fold in C7-deficient persons and about 700-fold in C9-deficient persons.³⁹⁶

The risk for infection is higher in patients with C5 deficiency than in those with deficiencies of other terminal proteins because, in addition to the role of C5 in initiating assembly of the membrane attack complex, the free C5 fragment, C5a, is important for leukocyte recruitment to sites of microbial invasion.^{15,53}

At least one episode of meningococcal disease occurs in approximately 60% of persons who have been identified as having C5, C6, C7, C8, or properdin deficiency, and 75% to 85% of documented bacterial infections in complement-deficient persons are meningococcal.^{166,208,471} Conversely, approximately 14% of patients presenting with sporadic meningococcal disease have a defect in one of the late complement components, and

this percentage rises to about one third among individuals with two or more meningococcal infections. The mortality due to meningococcal infection in such patients is lower than in normal persons, probably because patients with these deficiencies often have antibodies to meningococci that can activate the classical pathway leading to normal opsonization and phagocyte activation, which are effector functions upstream in the cascade from the membrane attack complex. In contrast, individuals with normal complement levels who develop meningococcal infection usually do so because they do not have specific antibodies with which to mobilize any effector functions via the classical pathway, and, as noted earlier, meningococci are poor activators of the alternative pathway.

Currently no specific treatment exists for patients with hereditary complement deficiencies. Replacement of missing complement proteins is not practical because of the short half-life of most of the components.^{52,329,474} Immunization of complement-deficient patients and their close household contacts against encapsulated organisms, especially *N. meningitidis*, is important.

Disorders of Phagocyte Function

General features of phagocyte disorders. The most frequently encountered reminder of the importance of an adequate supply of well-functioning phagocytes comes from patients who develop chemotherapy-associated neutropenia and are thus at high risk for bacterial and fungal infections.⁴⁴² The qualitative disorders of phagocyte function discussed in this section result in similar susceptibilities to these infections, either because the circulating cells are unable to migrate to an infected site or because, once having migrated to the infected tissue, they are unable to effect normal microbicidal activity. There is some overlap among the types of infectious complications associated with disorders of migration versus killing. However, as a rule, defects of neutrophil migration tend to be associated with infections at skin, subcutaneous tissue, and mucous membrane sites. In contrast, killing defects are more likely to result in infections of deeper soft tissues and internal organs, although skin infections are not uncommon.

Intrinsic disorders of cell migration

Type 1 leukocyte adhesion deficiency. In the late 1970s and the first half of the ensuing decade, several reports described patients with recurrent bacterial infections, diminished neutrophil motility, and delayed separation of the umbilical cord.^{1,28–30,34,145,213,257} The neutrophils of these patients were discovered to be markedly deficient in adherence to both natural and artificial surfaces, response to complement-opsonized particles, and expression of members of a family of heterodimeric glycoproteins: LFA-1, Mac-1, and p150,95, each defined by its own unique α subunit, CD11a, CD11b, and CD11c, respectively, but sharing a common 95-kDa β subunit designated CD18.^{29,30,34,35,523} A fourth α subunit, CD11d, whose importance remains poorly understood, has been described more recently. The defective expression of these proteins, also called the β_2 leukocyte integrins, appeared to be directly responsible for the striking adherence-dependent defects that characterized the function of leukocytes from patients with this disorder.^{28–30,34,35,523} Various called Mac-1 deficiency, MO1 deficiency, LFA-1 deficiency, CD11/CD18 deficiency, or CR3 deficiency, this disorder, now usually called type 1 leukocyte adhesion deficiency (LAD-1), is an autosomal recessive disorder with one of numerous mutations in the β_2 integrin subunit, CD18, localized to chromosome 21.^{30,35,523,524} It has been identified in more than 150 persons worldwide and encompasses a broad ethnic diversity.^{30,35} Patients may exhibit a moderate or severe phenotype, depending on the extent of the defect in protein expression.^{29,30} The documented mutations of the β_2 subunit (CD18) range from complete absence of the protein to extensions of the molecule, truncations of the extracellular portion or of the cytoplasmic domain of the molecule, small deletions, and point mutations.^{31,35,269}

Patients with LAD-1 develop recurrent necrotic skin and soft tissue infections with poor or absent pus formation, and they exhibit poor wound healing.^{20,29} They develop severe periodontitis, often losing their primary and secondary dentition along with alveolar bone.^{29,30,558} They may develop enterocolitis much like that seen in neutropenic patients.^{26,29} Delayed separation of the umbilical cord, presumably resulting from an impaired inflammatory response, is a common feature of the more

severe phenotype of this disorder,^{29,30} but this finding alone in infants without infectious complications or other characteristic features is of doubtful significance.⁵⁸⁶ Pronounced leukocytosis is a common feature of LAD-1, even in the absence of active infection.^{29,30} Recent studies in CD18-null LAD-1 mice reveal abnormally high circulating granulocyte colony-stimulating factor (G-CSF) levels and suggest the absence of a negative feedback mechanism on G-CSF production that occurs during normal transendothelial migration of leukocytes and involves IL-17. Absent ongoing transendothelial migration results in failure of this putative feedback mechanism, resulting in elevated G-CSF levels and higher circulating granulocyte counts.²¹⁶

Functional studies of neutrophils from patients with LAD-1 reveal a marked impairment of all adherence-dependent functions that require the β_2 integrins.^{28–30,107,227,269} PMNs and NK cells from patients with LAD-1 exhibit impaired ADCC for virus-infected target cells, suggesting that CD11/CD18-mediated cell-cell adhesion is essential for normal killing of virus-infected cells by this mechanism³¹⁰ and that the increased severity of viral infections in a few of the most severely affected patients could be related to defective ADCC. Currently the diagnosis of LAD usually is made by demonstrating absent or markedly deficient expression of the CD11/CD18 family of glycoproteins on circulating leukocytes by immunofluorescence flow cytometry.^{28–30,35}

Careful attention to skin and oral hygiene, aggressive management of infections, and meticulous local care of wound sites are important in the care of patients with LAD-1 or any serious disorder of neutrophil migration. The efficacy of prophylactic antibiotics has not been well established. Bone marrow transplantation with HLA-matched allogeneic marrow has had mixed results, from complete correction of the phagocytic defect to death 9 months after transplantation from graft-versus-host disease.^{30,213} The human CD18 gene has been cloned and sequenced, and human LAD-1 cells have been corrected successfully in vitro with the normal CD18 complementary DNA carried by retrovirus vectors, hinting at the future promise of gene therapy for patients with LAD-1.^{26,30,316}

Type 2 leukocyte adhesion deficiency. In 1992, two unrelated patients were reported, both products of consanguineous matings, who exhibited clinical characteristics virtually identical to those described for LAD-1.²¹⁹ However, expression of the β_2 (CD18) integrins on leukocytes was normal. In addition to defects in neutrophil motility, these children exhibited short stature, psychomotor retardation, and the Bombay (hh) erythrocyte phenotype (homozygous for absence of the H antigen). Phagocytosis by PMNs was normal. Recently it has been documented that this defect is due to one or more mutations of a specific guanosine diphosphate (GDP)-fucose transporter,³⁵⁴ resulting in the absence of fucosyl residues on sialyl Lewis X, the tetrasaccharide moiety that serves as the principal ligand for members of the selectin family of adhesion molecules.^{219,328,567} In vivo and in vitro studies comparing the adhesive functions of PMNs from LAD-1 and this new disorder, now called LAD-2, provided elegant validation of the distinct roles of selectins and integrins in the recruitment of leukocytes in vivo, with the initial selectin-mediated “rolling” stage (deficient in LAD-2) required first for the second integrin-mediated “firm adhesion and extravasation” stage (deficient in LAD-1) to occur (see Fig. 2.2).⁵⁶⁷ The other somatic and neurologic features of LAD-2 may be related to more widespread consequences of the generalized defect in fucosylation of glycoproteins.³⁵⁴

Type 3 leukocyte adhesion deficiency (integrin activation defect). During the past decade, several patients have been reported who have a clinical phenotype that includes features of both type 1 LAD and Glanzmann thrombasthenia, a bleeding disorder associated with mutations in the $\alpha_{IIb}\beta_3$ integrin on platelets. Laboratory studies of these patients revealed markedly deficient integrin-mediated adhesive functions of both leukocytes and platelets despite normal surface expression of both leukocyte and platelet integrins. Further studies led to the conclusion that this defect in integrin function was the result of defective “inside-out” signaling pathways that normally lead to integrin activation.^{196,305,366} Recent data on several kindreds with this disorder, studied in different laboratories, confirmed the presence of mutations in the gene encoding Kindlin-3, a molecule that, during cell activation, forms a critical bridge between the actin cytoskeleton and the cytoplasmic domain of the β

subunit of multiple classes of integrins expressed by cells of hematopoietic lineages.^{266,358,389,535} This bridging by Kindlin-3 is essential for normal integrin activation in both leukocytes and platelets.

Specific granule deficiency. Rare patients with hereditary specific granule deficiency have been reported, beginning with Spitznagel’s original description in 1972.^{86,222,521} These persons exhibited recurrent and severe infections, primarily of the skin and mucous membranes, sometimes involving the lung and, in one patient, the mastoid. Neutrophils from patients with this disorder exhibit absent specific granules on Wright-stained blood smears. Lactoferrin released from specific granules reduces the negative surface charge of the plasma membrane, contributing to nonspecific adhesiveness of the cell.²²² The specific granule membrane also contains some of the intracellular store of the important adhesion molecule Mac-1 (CD11b/CD18) that is mobilized to the plasma membrane upon cell activation.^{60,81} Recurrent skin and mucous membrane infections resulting from *S. aureus*, gram-negative bacilli, and *Candida* spp. characterize the natural history of patients with this disorder.^{86,222,521} Neutrophils in this disorder also exhibit diminished microbicidal activity, presumably because of diminished amounts of the cytochrome component of NADPH oxidase that normally reside in the membrane of specific granules. In this rare disorder, males and females are represented equally. A few patients with specific granule deficiency have a deletion in the gene encoding the myeloid cell transcription factor known as CCAAT/enhancer binding protein epsilon (C/EBP ϵ) with absent expression of this transcription factor, although not all patients with this disorder have a mutation of this gene.^{174,338}

Chédiak-Higashi syndrome. Chédiak-Higashi syndrome is a complex, rare autosomal recessive disorder characterized by partial oculocutaneous albinism, recurrent pyogenic infections, peripheral neuropathy, and neutropenia.⁷⁷ The illness also may involve an accelerated lymphoproliferative phase.⁷⁷ Granular cells, including neutrophils, contain giant lysosomal granules that are the apparent result of spontaneous intracellular fusion of azurophilic granules and, to a lesser extent, specific granules.⁷⁷ Corresponding disorders of intracellular pigment granules and vesicle trafficking in axons account for the albinism and other manifestations of this disease.⁷⁷ The genetic basis of the defect is now known to involve either a mutation in the gene encoding a large protein called the *lysosomal trafficking regulator* (LYST), homologous to the “beige” gene in mice, with all mutations studied so far resulting in a truncated protein.^{51,119} Patients with Chédiak-Higashi syndrome develop recurrent skin and mucosal infections, most often caused by *S. aureus*.^{30,77} A cell migration defect appears to be related to abnormal regulation of microtubule polymerization upon cell activation.⁷⁷ The possible role of intracellular levels of cyclic adenosine monophosphate and guanylic acid in this microtubule abnormality has been suggested.⁸⁹ Studies of two brothers with Chédiak-Higashi syndrome demonstrated abnormally increased tyrosinylation of the α subunit of tubulin.^{77,399} The diagnosis of Chédiak-Higashi syndrome usually is suspected clinically on the basis of partial oculocutaneous albinism and recurrent pyogenic infections. A Wright stain demonstrating giant lysosomal granules and laboratory studies showing defective cell migration are confirmatory, and genetic confirmation is now possible.

Neutrophil actin dysfunction. Filamentous actin constitutes the main contractile mechanism of neutrophils for migration and phagocytosis.⁵³⁰ An extremely rare and apparently heterogeneous disorder, neutrophil actin dysfunction has been characterized by recurrent skin infections caused by *S. aureus* and *Candida albicans*. In vivo and in vitro studies revealed severely impaired neutrophil chemotaxis and phagocytosis.⁸⁷ The capacity for polymerization of actin from cell extracts also was diminished markedly. It is of interest that PMNs from family members of this patient also were found to be variably deficient in the CD11/CD18 family of glycoproteins that are the basis of LAD-1.⁵¹⁸ One similarly affected infant was found to have abnormally high levels of a 47-kDa protein, now identified as *lymphocyte-specific protein-1* (LSP-1), which exhibits actin-binding activity.¹³²

Glycogen storage disease type 1B. Beaudet and colleagues⁵⁷ first reported the association of recurrent infection, neutropenia, and impaired neutrophil migration with glycogen storage disease type 1B, a metabolic disorder characterized by defective microsomal transport of glucose-6-phosphate. In 1985, Ambruso and coworkers¹⁹ reviewed

the features of 21 patients with glycogen storage disease type 1B, 15 of whom suffered from frequent infections, especially of the skin and subcutaneous tissues. Impaired neutrophil motility was found in 8 of 11 patients in whom this was evaluated. A specific relationship between the underlying metabolic defect in glycogen storage disease type 1B and the mechanism of impaired cell motility has not been established. However, exogenous glucose is an important energy source for chemotaxis,⁵⁷⁷ and it is interesting to note that the uptake of glucose by PMNs in response to chemoattractant stimulation is impaired in glycogen storage disease type 1B, as well as in neonates, both examples of patients with impaired PMN migration.^{4,53}

Extrinsic or secondary defects of polymorphonuclear leukocyte migration

Defective neutrophil chemotaxis associated with serum inhibitors of cell function. Investigators have reported the presence of inhibitors of PMN chemotaxis in the serum of patients with recurrent infection.^{315,507,517,559,575} In each case, the patient's neutrophils exhibited diminished chemotaxis in the presence of autologous serum or plasma, whereas identical assays in the presence of control serum or plasma resulted in a normal chemotactic response. Most such inhibitors appear to be immunoglobulins or immunoglobulin-like molecules.

Hyper-immunoglobulin E syndrome. In 1966, Davis and colleagues¹⁶⁰ described two young girls with coarse facial features, reddish hair, fair skin, severe eczema, dystrophic nails, "cold" staphylococcal skin abscesses, and recurrent sinopulmonary infections. The term *Job syndrome* was suggested, referring to the similar biblical affliction. Additional patients were described with a similar disorder, first associated by Buckley and associates¹⁰⁵ with very high serum IgE levels, including a patient who exhibited a defect in neutrophil chemotaxis reported in 1973 by Clark and associates.¹³¹ Features common to all of the patients with the disease now termed *hyper-IgE syndrome* include a history of staphylococcal infections of the skin and sinopulmonary tract beginning in infancy or early childhood and serum levels of IgE that are greater than 2000 IU/mL.^{100,105,179} Based on extensive reviews, other characteristic but variable features of this disorder include coarse facies, cold abscesses of the skin and subcutaneous tissues, a chronic eczematoid rash, eosinophilia, and mucocutaneous candidiasis.^{100,179,217} Consistent abnormalities of cell-mediated immune functions in patients with hyper-IgE syndrome suggest that the pathogenic basis involves a defect of T-cell regulation.^{104,126,179,230} An extensive study of 19 kindreds revealed autosomal dominant inheritance with a genetic locus for hyper-IgE syndrome on chromosome 4, in the proximal 4q region.^{246,247} In 2007, it ultimately was determined that this disorder can be attributed to dominant negative mutations in STAT3, a factor critical for signal transduction by at least 10 different cytokines, some with proinflammatory and others with antiinflammatory functions.^{272,381,519} The immunologic defect is characterized further by a paucity of T_H17 lymphocytes, which normally promote protective leukocyte responses to bacteria and fungi.³⁸² Recently a rare and clinically distinct autosomal recessive form of hyper-IgE syndrome has been described, resulting from a mutation in *DOCK8*, a member of a family of atypical guanine nucleoside exchange factors highly expressed in lymphocytes.⁵³³ Patients with this form of hyper-IgE syndrome have developed chronic viral infections, severe allergies, and early-onset malignancies.^{79,246,519,533}

Although hyper-IgE syndrome might more properly belong in discussions of defective T-cell regulation, some patients with hyper-IgE syndrome may have a defect in neutrophil chemotaxis.¹⁷⁹ The defect sometimes has been intermittent, and, in several cases, the presence of a serum inhibitor of chemotaxis has been recognized.^{178,179} Recent data suggest that keratinocytes and other epithelial cells from patients with hyper-IgE syndrome may produce reduced amounts of neutrophil-attracting chemokines, and neutrophils of these patients exhibit reduced expression of chemoattractant receptors.^{382,383}

Other secondary or poorly defined disorders of polymorphonuclear leukocyte migration. Patients with protein-calorie malnutrition have defective PMN chemotaxis that appears to be based on systemic preactivation of circulating cells resulting from chronic low-level endotoxemia from impaired intestinal mucosal integrity.^{122,484} Shwachman-Diamond syndrome, in addition to pancreatic insufficiency, neutropenia, and growth retardation, also is associated with defective PMN migration.¹⁰

Two kindreds with congenital ichthyosis and an associated defect of PMN migration have been described.³⁸⁰ Patients with severe thermal injuries develop an acquired form of specific granule deficiency with impaired PMN migration beginning about 14 days after injury.²²² Several reports have been published of a poorly defined disorder of neutrophil migration referred to as *lazy leukocyte syndrome*,^{9,378,379} marked by recurrent staphylococcal skin infections, rhinitis, gingivitis, stomatitis, neutropenia despite adequate marrow precursors, and diminished in vivo and in vitro migration of neutrophils.

Defects in phagocyte microbicidal activity. As described earlier, the broad array of available phagocyte microbicidal mechanisms may be divided into oxygen-dependent and oxygen-independent mechanisms. To date, no specific deficiency of any oxygen-independent microbicidal mechanism has been described. Thus this section is concerned mainly with the known deficiencies of oxygen-dependent microbicidal mechanisms of phagocytes, especially chronic granulomatous disease, the prototypical defect in this group. PMNs, monocytes, and the fixed phagocytes of the reticuloendothelial system generally share in the deficient microbicidal activity observed.

Chronic granulomatous disease. Chronic granulomatous disease (CGD) was one of the earliest syndromes of phagocyte dysfunction to be characterized.⁴⁴⁸ It is recognized now to be a family of biochemically and genetically heterogeneous disorders of distinct components of the phagocyte NADPH oxidase complex (see Fig. 2.3 and related text)^{122,174} that result in the inability of phagocytes to generate superoxide anion and other reactive oxygen species.¹⁷⁴ Organisms that produce catalase pose a special problem for patients with this disease.^{174,180,291,333} This encompasses a broad range of pathogens, including staphylococci, gram-negative enteric bacteria, *Pseudomonas* spp., yeast, fungi, *Nocardia* spp., and numerous other pathogenic species.^{180,289,333,588} Most microorganisms produce H₂O₂, which might be used, even by the CGD phagocyte, as an effective microbicidal weapon because it feeds into the sequence of oxidant reactions downstream from the defective oxidase enzyme (see Fig. 2.3).⁴⁶⁵ Organisms that produce catalase are able to survive within these deficient cells because catalase is an enzyme that degrades H₂O₂ to oxygen and water.^{291,466} Infections with catalase-negative bacteria, such as *Streptococcus*, *Haemophilus*, and *Neisseria* spp., do not occur with increased frequency in CGD patients,⁵⁸⁸ and these organisms are killed normally in vitro by CGD phagocytes. Phagocyte functions not directly related to oxidative mechanisms of intracellular killing, including adherence, chemotaxis, phagocytosis, and degranulation, usually are normal.^{42,381,448,515}

The genetic defect in CGD may be inherited by either X-linked recessive or autosomal recessive mechanisms.^{83,130,151} In the report of a registry of 368 patients with CGD in the United States,⁵⁸⁸ more than two-thirds of the patients had the X-linked recessive form with absent gp91^{phox}, the larger subunit of the cytochrome b₅₅₈; about 12% had an autosomal recessive form with absent cytosolic p47^{phox}; and fewer than 5% each had autosomal recessive disease with absent cytosolic p67^{phox} or absence of p22^{phox}, the smaller subunit of the cytochrome b₅₅₈. Approximately 12% had an unknown genetic form of the disease. A single individual with an autosomal recessive form of CGD due to mutations in the cytosolic p40^{phox} has been reported.³⁶⁴ About 5% of patients with CGD have normal levels of an abnormal protein that is inactive, and at least 410 different mutations have been reported to result in CGD.²⁶⁴ These genetically diverse defects all result in defective function of the oxidase and the characteristic CGD phenotype. In the female obligate carriers of X-linked CGD, the proportion of cells that express the defect usually is between 35% and 65%, depending on the proportion of cells in which random inactivation of the normal versus the affected X chromosome occurs.^{355,588} Overall, patients with X-linked disease have more severe courses and experience higher yearly death rates than patients with autosomal recessive forms of the disease.⁵⁸⁸

Patients with CGD experience recurrent serious bacterial and fungal infections, usually beginning in the first few months of life. *S. aureus* and gram-negative bacilli, especially *Serratia marcescens* and *Burkholderia cepacia*, are the most common causes of infection in patients with CGD. Fungi, especially *Aspergillus* spp., also are prominent etiologic agents,^{333,453,588} and infections caused by *Aspergillus* are the most common cause of death in these patients.⁵⁸⁸ Granuloma formation at infected

sites is one of the histologic hallmarks of this disorder.^{290,453} Pulmonary infections and their complications have been the reported cause of death in up to 50% of these patients in some series, and *Aspergillus* predominates.⁵⁸⁸ These infections often are protracted and respond slowly to appropriate antibiotic therapy.^{291,453} Progression to lung abscess, empyema, or both occurs in about 20% of patients with CGD with pneumonia.²⁹¹ Liver abscesses occur in about half of patients and may be recurrent.^{59,127} The hepatosplenomegaly common in CGD may result from these infections but more likely results from chronic infections at various sites with systemic lymphoid hyperplasia.^{45,291} Osteomyelitis occurs in about one third of patients.^{291,453,588} In contrast to normal children, in whom this infection usually involves the metaphyseal area of long bones, patients with CGD more often develop infections of the small bones of the hands and feet. In normal children, *S. aureus* is the most common etiologic agent and causes a significant proportion of cases in CGD. However, gram-negative bacilli and *Aspergillus* appear to be the predominant etiologies, and other agents, including *Nocardia*, also may be important etiologic agents of bone infection in CGD.^{437,588} Skin infections in this disorder may include pyoderma, purulent dermatitis, and cutaneous or subcutaneous abscesses and often are preceded by a chronic eczematoid skin rash.⁴⁵³

Although localized infections are the rule in patients with CGD, these patients also may develop septicemia.^{291,453,588} The most common cause of septicemia in most series has been *Salmonella*, but other gram-negative enteric bacilli also have been prominent.^{290,333} Of note, *S. aureus* is a proportionally less common cause of septicemia in these patients.^{453,588}

Granuloma formation adjacent to hollow viscera in patients with CGD can produce clinically significant obstruction, including obstruction of the gastric outlet, esophagus, small intestine, and ureters. This complication usually responds to treatment with corticosteroids.^{20,180,588}

CGD should be suspected in patients with a history of recurrent indolent infections caused by catalase-positive organisms such as those

described earlier, especially if granulomas are found in biopsy specimens of lymph nodes or other tissues. Confirmation of the diagnosis usually rests on the demonstration of an absent or nearly absent oxidative metabolic burst in the patient's phagocytes. This can be detected classically by the slide NBT test or by various other measurements of oxidative burst activity, most recently by flow cytometry of PMNs loaded with oxidant-sensitive fluorescent dyes.^{13,40,54,465,548} Fig. 2.10A is an example of the slide NBT test in an X-linked carrier; Fig. 2.10B is an idealized set of flow cytometry histograms with typical patterns for a normal control, a patient with CGD, and both X-linked and autosomal recessive carriers. Prenatal diagnosis has been achieved by the use of the slide NBT test with blood from placental vessels obtained at fetoscopy.⁴⁰¹

The management of patients with CGD includes antibiotic prophylaxis, usually with trimethoprim-sulfamethoxazole, and an aggressive approach to the specific diagnosis and treatment of acute infections.⁴⁵³ Antifungal prophylaxis with itraconazole or voriconazole that has activity against *Aspergillus* also has become standard. Bone marrow transplantation met with early limited success,^{241,298,581} but allogeneic peripheral blood stem cell transplantation from HLA-identical sibling donors, with prior myeloablative conditioning, has been considerably more promising, as suggested by the European experience from 1985 to 2000, with 22 of 23 patients "cured" at median follow-up of 12 years.⁴⁹⁵

A multicenter study reported that daily subcutaneous injections of IFN- γ reduced the requirement for hospitalization of CGD patients for serious infections by about two-thirds.²⁸³ The mechanism by which IFN- γ exerts its beneficial effect in CGD has not been determined. Despite some systemic side effects, such as fever, fatigue, and myalgia,²⁸³ it generally has been well tolerated,³⁶⁰ and it continues to be used in the management of many patients with this disorder.⁵⁸⁸

Deficiencies of glucose-6-phosphate dehydrogenase, glutathione peroxidase, and glutathione synthetase. The normal activity of the NADPH oxidase enzyme complex depends on the continued availability of NADPH to reduce molecular oxygen to form superoxide anion.^{129,465} The primary source of NADPH for this enzyme is the hexose

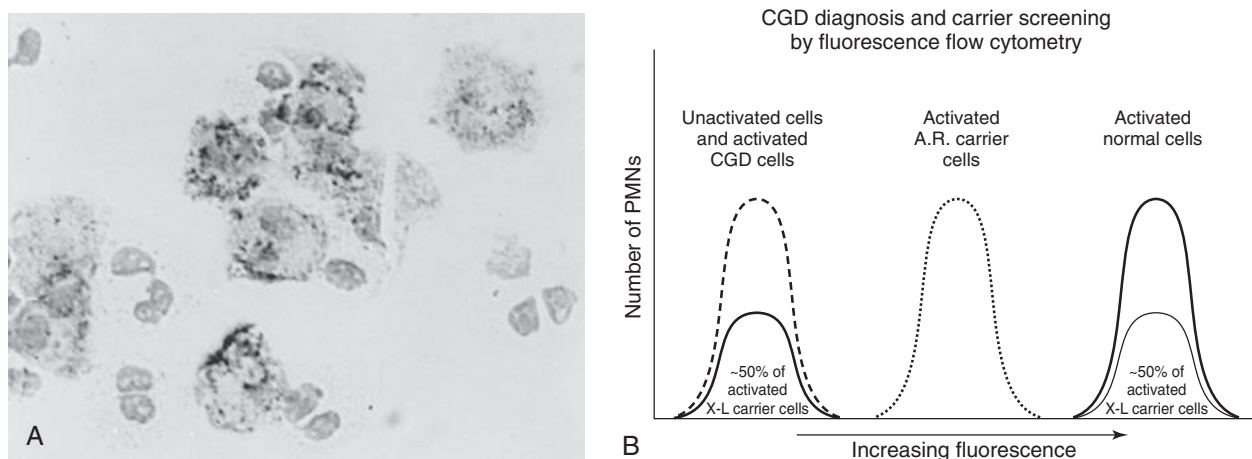

FIG. 2.10 (A) Photomicrograph of a slide nitroblue tetrazolium (NBT) test of polymorphonuclear leukocytes (PMNs) isolated from the blood of a maternal carrier of X-linked recessive chronic granulomatous disease (CGD). Because of random inactivation of either the normal or the affected X chromosome in maternal carriers of this disorder, approximately half of the PMNs exhibit the granular blue-black staining characteristic of the oxidative reduction of NBT by normal PMNs. In contrast, the remaining PMNs, which express the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase defect of CGD, are visible only by their nuclear counterstain. (B) Flow cytometry in CGD diagnosis and carrier testing. These idealized flow cytometry histograms demonstrate the oxidative burst activity of populations of PMNs that have been loaded with an agent such as dihydrorhodamine that becomes fluorescent when it reacts with products formed during the oxidative burst. The taller curve on the far left represents the fluorescence typical of both inactivated normal PMNs and activated PMNs from a patient with CGD with an absent oxidative burst. The taller histogram on the far right demonstrates the increased level of fluorescence exhibited by activated normal PMNs. The two smaller curves on the left and the right represent the two populations of activated PMNs from a typical maternal carrier of X-linked CGD, indicating about 50% normal PMNs and 50% expressing the defect. The taller histogram in the middle represents typical results for the cells of a carrier of autosomal recessive CGD, with all cells exhibiting an intermediate level of fluorescence.

monophosphate shunt, and this pathway is provided with the hexose substrate, 6-phosphoglucose, by the enzyme glucose-6-phosphate dehydrogenase (G6PD), which also generates NADPH in a coupled reaction.⁴⁶⁶ The reactions of the hexose monophosphate shunt itself are coupled to two other enzymes, glutathione reductase and glutathione peroxidase, which recycle oxidized and reduced glutathione.⁴⁶⁵ A deficiency in any of these three enzymes results in a lack of available NADPH to drive the NADPH oxidase and may result in a phagocyte killing defect similar to CGD.^{41,477} G6PD deficiency usually involves erythrocytes and is associated with hemolytic anemia, especially in conjunction with the administration of sulfonamides.¹⁴² Only when the defect also involves myeloid cells and is severe or complete (<5% of normal enzyme levels) is the CGD-like disorder manifested.^{41,477} A partial deficiency of glutathione reductase has been reported, presenting with hemolytic anemia and early cataracts, but no increased incidence of infection was noted.⁴⁶⁴

The synthesis of an adequate supply of glutathione also is critical to these cells. Two brothers with glutathione synthetase deficiency who presented with neutropenia, hemolytic anemia, acidosis, 5-oxyprolinuria, and recurrent infection were reported by Spielberg and colleagues⁵²⁰ and Boxer and associates.⁸⁸ The PMNs from these patients exhibited elevated cytosolic hydrogen peroxide levels, diminished oxidative microbicidal activity, and impaired microtubule assembly. Antioxidant therapy with vitamin E normalized the in vitro abnormalities of the patients' PMNs, with no further difficulty with recurrent infections.⁸⁸

Myeloperoxidase deficiency. Congenital deficiency of neutrophil myeloperoxidase has come to be recognized as the single most common heritable disorder of neutrophil function, occurring in about 1/2000 persons.^{400,435} The precise mode of inheritance of this defect has not been established, but myeloperoxidase is known to be a product of a single gene on chromosome 17.⁵⁶⁰ Although PMNs from some patients with myeloperoxidase deficiency have been found to exhibit delayed killing of *C. albicans* and *S. aureus*, myeloperoxidase deficiency rarely has been associated with unusual infectious complications.

Important Examples of Secondary Immunodeficiency (Excluding Human Immunodeficiency Virus Infection)

Asplenia

Fulminant infections can occur in patients who have anatomic or functional asplenia.⁷⁸ The mortality rate from these infections in asplenic persons ranges from 40% to 80%.^{78,587} The most common pathogens are encapsulated bacteria, including *S. pneumoniae* (50–70%), *H. influenzae*, and *N. meningitidis*.⁵⁸⁷ Other streptococci, *S. aureus*, *Salmonella*, and other gram-negative bacilli are important but less common pathogens. Malaria and babesiosis also are more severe in asplenic persons. Infections can occur at any time but are most common within the first 2 years after splenectomy.

Both the liver and the spleen are important in phagocytic clearance of bacteria from the circulation, and the spleen is an important site for antibody production. Young children who become asplenic are much more susceptible to fulminant infection than are adults because adults are more likely to have encountered antigens before splenectomy than are children. Persons whose indication for splenectomy is thalassemia or Hodgkin disease are at higher risk for dying of overwhelming infection than are those who develop functional asplenia from sickle-cell disease. Patients who undergo spleen removal for spherocytosis or idiopathic thrombocytopenia have a lower risk for infection. The lowest risk group consists of individuals whose spleens are removed surgically after trauma.^{78,138}

Congenital asplenia usually is associated with complex congenital cardiac disease and occasionally with structural abnormalities of the gastrointestinal or genitourinary tracts. Thus asplenia should be suspected in any patient with congenital heart disease and sepsis resulting from encapsulated organisms. Anatomic or functional asplenia also should be suspected in patients whose erythrocytes are found to contain Howell-Jolly bodies because these typically are removed from the circulation by the normally functioning spleen. Ultrasound or radionuclide liver and spleen scan usually can confirm asplenia or significant hyposplenia.⁷⁸

Asplenic persons are managed using prophylactic antibiotics, usually penicillin V or amoxicillin, until at least 5 years of age.¹³⁸ They also should be immunized against encapsulated organisms at the appropriate ages (e.g., *H. influenzae* type b and pneumococcal conjugate vaccines and meningococcal conjugate vaccine beginning at 2 months), and heightened attention to clinical evaluation and treatment of febrile episodes is recommended.^{138,473} Patients should be warned about the increased risk for serious infections from malaria and babesiosis.

Sickle-Cell Disease

Immunodeficiency in sickle-cell disease patients is due in large part to their functional asplenia.⁴⁸⁴ Part of the risk for infection stems from local infarction and tissue necrosis resulting from sickling, which causes sludging and resultant tissue hypoxia. The reticuloendothelial system also may be obstructed by having to deal with chronic hemolysis. Patients with sickle-cell disease experience a high incidence of sepsis and meningitis caused by encapsulated organisms (e.g., *S. pneumoniae*, *H. influenzae* type b, *N. meningitidis*) and *Salmonella*.²¹⁵ *Salmonella* infections often are associated with osteomyelitis.¹⁹³

Patients with sickle-cell disease appear to have normal antibody responses to most antigens, including age-appropriate responses to vaccines, and they usually have normal complement function.²⁸⁹

Patients with sickle-cell disease should be managed with prophylactic antibiotics until at least 5 years of age and should be immunized against *H. influenzae* type b, pneumococci, and meningococci at the appropriate ages.¹³⁸

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder caused by mutations in both alleles of the gene encoding the protein called cystic fibrosis transmembrane conductance regulator (CFTR), a cyclic AMP-regulated chloride channel expressed at the luminal surface of airway epithelial cells.⁵⁷⁹ Most patients with CF develop chronic endobronchial infection with *P. aeruginosa* of the mucoid phenotype. This infection is accompanied by an intense chronic airway inflammation with an exuberant influx of neutrophils that leads to bronchiectasis and destruction and fibrosis of lung and airway tissue and early death.^{124,312} The airway inflammatory milieu, including neutrophil-derived proteases such as elastase, contributes to secondary impairments in opsonic and phagocytic host defenses by cleaving opsonic antibody and complement fragments, as well as important phagocytic receptors for these opsonins.⁵⁵⁰ Mucociliary clearance of bacteria from the CF airway is impaired because of viscous, dehydrated epithelial lining fluid, and large quantities of DNA from dying neutrophils impair clearance of secretions by further enhancing their viscosity. The unresolved question of the relationship between the cystic fibrosis genetic defect and the pathogenesis of *Pseudomonas* chronic lung infection continues to stimulate active research.^{124,441,480,511} Diagnosis of CF is classically made by documenting elevated levels of sweat chloride, but genetic diagnosis is now undertaken more frequently. Management of patients typically includes nutritional support, pancreatic enzyme replacement, frequent aggressive chest physiotherapy to mobilize secretions, intermittent courses of aerosolized tobramycin, aggressive management of pulmonary exacerbations, and recombinant aerosolized DNase to help liquefy secretions. Gene therapy has been explored but has not resulted in correction of the defect at the clinical level. Recently a novel and promising trial of pharmacotherapy targeted the basic defect in CF. The drug ivacaftor, an orally administered potentiator of CFTR chloride channel function in CF patients with at least one G551D-CFTR mutation, resulted in sustained improvement of lung function through 48 weeks of treatment; ivacaftor is now licensed for CF patients with this mutation.¹⁹⁰

Ciliary Dyskinesia

Primary ciliary dyskinesia is a rare disorder of deranged ciliary motility that predisposes patients to recurrent respiratory infections such as otitis media, sinusitis, bronchitis, and pneumonia as a result of poor clearance of secretions.⁵²⁹ It is due to a mutation in one of several genes encoding for a component of either the dynein arms or radial spokes of the cilia that provide the energy, movement, and structural integrity of the specific tubulin structures that make up the normal cilia of

respiratory epithelium.⁵²⁹ Approximately 50% of these patients may have dextrocardia and situs inversus. In the absence of these features, this disorder should be suspected in patients who have recurrent infections, as noted earlier, but who have undergone a comprehensive evaluation of humoral immunity that has not detected an abnormality. Diagnosis ordinarily requires a brush biopsy of nasal epithelial cells, best evaluated by transmission electron microscopy, which usually will reveal an abnormality of the inner or outer dynein arm or of the radial spokes of the cilia.^{503,529} Patients in whom this diagnosis is suspected should be referred to clinicians with expertise at centers with the capability to perform the necessary diagnostic studies. Long-term management can be challenging and often involves antimicrobial prophylaxis and attempts to assist in mobilization of secretions. Many of these patients develop bronchiectasis as a result of recurrent and chronic airway and lung infection. There is no specific treatment for the ciliary dysfunction.⁵²⁹

EVALUATION FOR IMMUNODEFICIENCY IN THE CHILD WITH RECURRENT OR SEVERE INFECTIONS

Most immunodeficiency disorders can be diagnosed readily by employing a methodical process that begins with careful analysis of the child's presenting history and physical examination.^{140,147,167,484,486} This information serves as the foundation, when indicated, for a rational laboratory evaluation. It should be borne in mind that it is normal for children to have several infections every year. It is not unusual for normal children who are exposed to other children, particularly older school-aged siblings or classmates, to develop approximately one infection per month, especially from late fall to early spring, when respiratory viruses are most active. The overwhelming majority of infections in immunocompetent children are characterized by being mild and localized to the gastrointestinal or upper respiratory tracts, and they either are self-limited or respond rapidly to conventional therapy. Immunocompromised hosts tend to have more frequent, severe, and unusual infections that may not respond readily to appropriate therapy.

History

A detailed history alone often is sufficient to determine whether an immunologic evaluation should be pursued in many children who have recurrent or severe infections. If tests for immunity are indicated, the history also serves as a guide to the types of studies that should be performed initially.

The age of onset of suspicious infections usually helps in defining the underlying problem. For example, children with isolated immunoglobulin deficiencies tend to do well during the first few months of life because they are protected by maternal antibody. They usually start developing serious infections later in the first year of life. Those with cell-mediated or phagocytic disorders may begin developing infections in the newborn period (see earlier discussion). In contrast, healthy children who have been cared for at home by their mothers and who have no siblings often have relatively few infections in the first few years of life but may be brought to the physician for immunologic evaluation when they develop recurrent respiratory tract infections beginning the first few weeks after entering daycare, nursery school, or kindergarten because of new exposure to various respiratory viral pathogens.

The number, nature, etiology, and severity of infections help in determining how aggressively to pursue an immunologic evaluation. Certain clinical presentations of disease and causative organisms are associated with a high likelihood of an immunodeficiency. Antibody or complement deficiencies or functional asplenia should be suspected in children with recurrent or life-threatening infections such as sepsis and meningitis caused by encapsulated organisms (e.g., *S. pneumoniae*, *H. influenzae* type b).^{98,167,289,335,467} Complement deficiencies should be considered in persons with recurrent or severe neisserial disease.¹⁶⁷ CGD should be suspected in the presence of recurrent or unusual deep tissue infections, such as liver abscess, lymphadenopathy, pneumonia, or osteomyelitis, especially when caused by unusual gram-negative bacteria, such as *Serratia marcescens*, or by *Aspergillus* species.⁵⁸⁸ Bacterial skin infections in patients who have never formed pus at infected sites may

suggest a leukocyte adhesion deficiency. Pneumonia caused by *Pneumocystis* suggests a T-cell deficiency, either hereditary or as a result of HIV infection. In contrast, recurrent or even severe infections with group A streptococcus have not been associated with immunodeficiency, and recurrent urinary tract infections usually are associated with anatomic abnormalities of the urinary tract rather than immunodeficiency.

Documentation of the child's growth pattern is essential because children who are thriving are much less likely to have serious immune disorders than are those with failure to thrive.

The immunization history should be documented carefully because it may prove useful in evaluating the child's ability to mount an antibody response to specific vaccine antigens. The history of recent live viral immunization should be obtained in children who have clinical presentations compatible with polio or measles because infection caused by vaccine strains of these viruses may be the first indication of immunodeficiency in some children.

Children who attend daycare facilities or preschools are constantly being exposed to common infections. Familiarity with community patterns of disease such as prevalent clinical manifestations of enterovirus infection or the beginning of croup, respiratory syncytial virus, influenza, or rotavirus seasons can be used to reassure families of normal children with frequent mild infections.

A detailed family history should be obtained that includes questions about the presence of immunodeficiency, recurrent or severe infections, contributing factors to any early deaths, the gender of affected persons, and consanguinity. A history of recurrent or severe infections in maternal male relatives should be given special attention because of the prominence of X-linked disorders among the primary immunodeficiencies. Auto-immune diseases might suggest a familial disorder of complement or cell-mediated immunity.¹⁶⁷

Physical Examination

Physical examination may provide valuable clues to the nature of an immune disorder. In certain cases, such as some patients with the hyper-IgE syndrome^{100,268} and the DiGeorge syndrome,¹⁷³ the characteristic facies may suggest the diagnosis.

As noted earlier, one of the most obvious signs that a child may have a serious underlying medical problem is failure to thrive. Every immunologic evaluation must include documentation of current growth parameters and comparison with past growth.

Many immunodeficiency disorders have dermatologic manifestations. Eczematoid rashes are seen in patients with the hyper-IgE syndrome and CGD.^{100,268} CGD and leukocyte adhesion deficiencies also are characterized by slow wound healing and abnormal scarring patterns.⁵⁸⁸ Patients with Chédiak-Higashi syndrome have partial albinism.⁷⁷ Severe gingival disease and early loss of teeth are prominent clinical features in disorders of neutrophil migration, such as LAD.^{27,33}

The chest should be evaluated for physical signs of active disease, such as rales and rhonchi, as well as evidence of chronic infection, such as an increased anterior-posterior diameter. Pneumonia, bronchitis, bronchiectasis, and scarring can occur with many immunodeficiencies but are associated most frequently with immunoglobulin deficiencies.^{98,259}

Cardiac abnormalities may be associated with primary asplenia or immunodeficiency disorders such as DiGeorge syndrome,¹⁷³ and dextrocardia with situs inversus should suggest ciliary dyskinesia as a cause of recurrent infections.¹⁴⁰

Although hepatosplenomegaly may be found in many types of primary immunodeficiency diseases, it is more common in patients with disorders of phagocyte function, especially CGD.⁵⁸⁸

Laboratory Studies

The laboratory evaluation should be guided by the history and physical findings. Relatively simple and inexpensive screening tests often can help narrow the differential diagnosis and streamline the evaluation. One of the first tests that should be performed is a complete blood count with differential and evaluation of the blood smear. This simple test can detect several immunologic abnormalities, including neutropenia, lymphopenia associated with HIV-1 or forms of SCID, the abnormal neutrophil granules associated with the Chédiak-Higashi syndrome,

Howell-Jolly bodies found with asplenia, and some malignancies. Chest radiographs should be examined for thymic tissue, mediastinal lymphadenopathy, pneumonia, bronchiectasis, and other evidence of chronic pulmonary infections. Consideration also should be given to evaluating patients with chronic pulmonary disease for CF with a sweat chloride test.

In most patients, the specific clinical features of infections and their etiologies provide an optimal guide to choosing the most relevant and specific laboratory tests for evaluating for immunodeficiency when this is indicated. All too frequently, a comprehensive and expensive evaluation of every major aspect of immunity is undertaken for a patient whose clinical presentation suggests a more carefully considered and targeted approach.

Children with a clear history of recurrent bacterial otitis media, sinusitis, or pneumonia are candidates for evaluation of humoral immunity by measuring levels of the major classes of immunoglobulin and IgG subclasses. Enumeration of B cells and marker studies by immunofluorescence flow cytometry should be considered if more severe forms of humoral deficiency, such as XLA or some forms of CVID, are suspected. Very high IgE levels may be helpful in establishing the diagnosis of hyper-IgE syndrome; it should be noted that many laboratories do not include IgE levels in the standard Ig quantitation, and this must be ordered separately. Children who have normal quantitative Ig and IgG subclass levels but who continue to have frequent sinopulmonary infections that do not respond well to appropriate medical and surgical management (e.g., ventilation tubes) also can be evaluated by measuring antibody responses to specific antigens such as tetanus and diphtheria toxoids, *H. influenzae* type b, and meningococcal and pneumococcal capsular polysaccharides. Antibody levels can be measured before immunization and approximately 1 to 2 months after immunization to evaluate the child's ability to respond to different kinds of antigens, including T-cell-dependent antigens, such as diphtheria and tetanus toxoid, or T-cell-independent antigens such as unconjugated pneumococcal capsular polysaccharide vaccine. In a patient with recurrent bacterial respiratory infections in whom no antibody-related abnormality can be identified after a comprehensive evaluation, the possibility of ciliary dyskinesia should be considered and a brush biopsy of nasal epithelial cells performed for electron microscopic studies (see earlier discussion).

The complement system should be evaluated in persons with recurrent or life-threatening neisserial disease, including systemic gonococcal infections and sporadic meningococcal disease. The best screening test for hemolytic complement is the CH₅₀. A normal CH₅₀ reflects a normal quantity and function of classical pathway proteins (C1, C4, C2), C3, and terminal components through C8, as noted earlier.¹³⁴ An abnormal CH₅₀ should be confirmed, being careful that the specimen is handled correctly. If a very low CH₅₀ is confirmed, it is important to determine both the serum levels of individual complement proteins and their functional activity in consultation with a reference laboratory.

In patients with infections suggesting a T-cell defect, such as *Pneumocystis*, *Cryptococcus*, or recurrent candidiasis, delayed hypersensitivity skin testing with antigens such as *Candida* or mumps may be useful to screen cell-mediated immunity, but results are not always reliable. Lymphocyte subset quantitation may be helpful in diagnosing such conditions as SCID, but more sophisticated testing of lymphocyte function such as mitogen and antigen stimulation should be performed in patients with recurrent or severe fungal infection or in whom CVID is suspected. Such studies ideally should be directed by a clinical immunologist.

Similarly suspected phagocyte function disorders should be evaluated in consultation with experts in phagocyte function because lack of proper standardization and expertise often produces misleading results from commercial laboratories. Phagocyte function studies should be directed toward defects of adhesion and migration in patients with recurrent skin and mucosal infections, poor or absent pus formation, and persistent leukocytosis suggestive of a leukocyte adhesion defect. Tests of oxidative metabolic activity and killing should be performed in patients with recurrent staphylococcal or unusual gram-negative or fungal tissue infections suggestive of CGD.

When clinical suspicion of an inherited immunodeficiency is confirmed by appropriate functional laboratory studies, it may be desirable to arrange for specific genetic testing to determine the precise nature of a patient's genetic mutation or variation when such testing is available. This may assist greatly in subsequent genetic counseling and will add important information to the clinical database on patients with the specific disorder.

Prevention of Infection

Patients and household members should be immunized with appropriate vaccines as soon and as fully as possible after a diagnosis of a family member with an immunodeficiency.¹³⁸ Although many immunodeficient patients, such as those with XLA or SCID, cannot respond normally to vaccines, immunization of household members and other close contacts may reduce the patients' risk for infection. Patients with complement deficiencies, asplenia, and sickle-cell disease should be immunized with vaccines directed against encapsulated organisms, such as meningococci, pneumococci, and *H. influenzae* type b. However, it should be remembered that these persons may not have normal responses to immunization and, therefore, if possible, their antibody responses to these vaccines should be measured; if responses are poor, they may benefit from additional doses of the vaccines. Live viral vaccines should not be administered to most patients with primary defects of cell-mediated immunity.

Patients with disorders characterized by recurrent or severe bacterial or fungal infections may require prophylactic antibacterial or antifungal therapy. Although this is an essential component of management for many of the more severe immunodeficiencies, such as DiGeorge syndrome, SCID, and CGD, the benefit of this approach has not been documented for all immune disorders. For many other disorders the uncertainty of the benefits of long-term antimicrobial prophylaxis must be weighed carefully along with the risk for emergence of antimicrobial resistance.

Prospects for Correction of Serious Primary Immunodeficiencies

Bone marrow or stem cell transplants have been successful in a few patients with specific immunologic disorders, including SCID,^{103,118} Wiskott-Aldrich syndrome,⁴²⁸ LAD, and CGD.^{30,213,581} Current protocols for thymus transplantation are showing great promise in treatment of patients with DiGeorge syndrome.³⁶¹ Gene therapy has raised new possibilities for correcting certain immunologic defects, having demonstrated early promise for some forms of SCID and early success in animal models of CGD.^{174,446} The development of malignancies associated with retroviral gene therapy in some cases has raised serious concerns about the ultimate feasibility of this approach,^{102,446} but the means of overcoming these and other potential obstacles to gene therapy continue to be sought.

Host Response to Infections: The “-omics” Revolution

3

Asuncion Mejias • Octavio Ramilo

INTRODUCTION

There has been tremendous progress in our attempt to discern the molecular basis of infectious diseases, yet several gaps remain both in the understanding of disease processes and in the development of optimal strategies that would allow early diagnosis and targeted treatment. In addition, despite major advances in the development and implementation of vaccines and antimicrobial agents, infectious diseases continue to represent a major cause of morbidity and mortality worldwide.¹²⁸ Recent examples such as the 2009 H1N1 influenza pandemic,^{30,121} the MERS coronavirus and enterovirus-D68 outbreaks, the West Africa Ebola and the Zika virus epidemics,^{111,143,148,197,220} as well as the increased frequency of hospital-acquired infections caused by multiple-resistant gram-negative bacilli⁷⁸ and highly virulent strains of *Clostridium difficile*¹⁹⁸ highlight the challenges we encounter when managing patients with infectious diseases. In this context of outbreaks of emergent and reemergent pathogens linked to increased antimicrobial resistance, there is a clear need for improved diagnostic tools for optimal patient classification and management.¹⁴²

HOST RESPONSES FOR IMPROVING THE DIAGNOSIS OF INFECTIOUS DISEASES

One of the most frequent challenges that physicians face in the clinical setting is the difficulty of establishing an appropriate etiologic diagnosis or even distinguishing between bacterial or viral infections in patients presenting with an acute febrile illness. These obstacles can delay initiation of appropriate therapy, which can result in unnecessary morbidity and even mortality. On the other hand, the need to promptly start appropriate antimicrobial therapy to control the infection has to be balanced with a rational use of antibiotics. Within this context there is an obvious need for improved diagnostics tools to help with patient classification, which in turn should allow appropriate use of targeted therapies.

Microbial pathogens are detected in clinically relevant specimens using a variety of assays including cultures, rapid antigen detection tests, and polymer chain reaction (PCR) assays. To date, to be able to establish causality, growing the specific pathogen (bacteria, virus, or fungus) remains the gold standard. However, this is a flawed approach, particularly if the organism is not present in the blood or from other easily accessible sites. In addition many pathogens grow slowly or require complex media, and a significant number of clinically important microbes remain unrecognized because they are resistant to cultivation in the laboratory, thus limiting clinical decision-making.^{45,190} The introduction of more sensitive molecular diagnostic assays has significantly improved the diagnosis of viral infections.⁹⁹ Unfortunately this is not the case for bacterial pathogens. Moreover, in the clinical setting, it is not uncommon to encounter situations in which the sole identification of a pathogen is not sufficient to establish causality (e.g., the detection of respiratory viruses in patients with no respiratory symptoms or in patients with pneumonia who often also have a co-detected bacterial pathogen).

In view of these limitations, for almost a century, there has been a large quest to identify host-derived biomarkers indicative of infection, such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP).^{223,231} These tests, which are useful in certain clinical scenarios, have proved to be nonspecific and are unable to differentiate between pathogen types (i.e., viral vs. bacterial) or even between infectious and noninfectious diseases. More recently, procalcitonin (PCT), a 116-amino acid protein produced in the thyroid and lungs, has shown improved sensitivity and specificity for the diagnosis of bacterial infections.^{7,22,72,149} Nevertheless, there are limitations and uncertainty about

its utility because serum concentrations of PCT also increase after surgery, trauma, cancer, or severe burns, thus raising the concern of false positives.^{97,154} Other candidate biomarkers have been used for the diagnosis of neonates and older children with sepsis and have produced inconsistent results because data have yet to be validated in independent cohorts.²⁰⁷

There is a need for an alternative strategy that has sufficient sensitivity to differentiate infectious from noninfectious conditions, sufficient specificity to distinguish among the different types of pathogens, useful to monitor response to therapy, and, ideally, is able to predict clinical outcomes. An alternative approach to the pathogen-detection strategy is based on a comprehensive analysis of the host response to the infection caused by different pathogens (Fig. 3.1).^{34,104,141,142,186,187} A wide range of molecular and cellular profiling assays are currently available for the study of the human immune system.³³ Genomics provide information about structural DNA changes and thus the probability of developing a condition, epigenetics describe the chromatin modifications that are caused by external or environmental factors and stably alter gene expression without changing the DNA sequence, transcriptomics study the overexpression or underexpression of genes (mRNA expression profiles) in a qualitative and quantitative manner in response to the infection, and metabolomics and proteomics analyze the structure, function, and interaction of posttranslational metabolites produced by a particular gene (Fig. 3.2). Thus the information provided by the “-omics” technologies is complementary, and their use for diagnostic, pathogenetic, or prognostic purposes is mainly limited by the available technology and complexity of the analyses (Fig. 3.3).

Independent of the -omics approach used, four tenets must be considered when using these tools for biomarker discovery to assure that the profiles are representative of the disease process and not of a confounding event: (a) selection and definition of the cases, which should be homogeneous in terms of the disease process and with limited confounders to allow interpretation of the multidimensional data; (b) need for controls, which should be also homogeneous, free of confounders, and similar in terms of the basic characteristics (i.e., demographic parameters) with the cases; (c) type of sample, which should reflect and change because of the biologic process and should be easy to obtain, ideally in a noninvasive manner; and (d) need for validation, to confirm that the profiles identified perform well in an independent cohort of patients that is different from the one used for the discovery phase. Of all these technologies, genomics and transcriptomics are moving into the clinical laboratory and are poised to become part of routine diagnostics in the next few years. In this chapter, we will review the application of analysis of host response through genomics, epigenetics, transcriptomics, proteomics, and metabolomics for diagnosis, understanding disease pathogenesis, patient classification and management, and possibly prognosis of pediatric patients with infectious diseases.

GENOMICS

The human genome, which is relatively static, is organized into 46 chromosomes consisting of 22 pairs of autosomal chromosomes shared by males and females and the sex-determining chromosomes, X and Y. One set of autosomal chromosomes is derived from each parent. Human genes are formed by *exons*, which are the coding regions, and *introns*, the noncoding regions. During transcription, the entire gene is copied into pre-mRNA, which includes exons and introns. Through the process of RNA splicing, introns are removed and exons joined to form a contiguous coding sequence. Single genes are able to generate 4 to 6 different mRNAs; thus many of the complex biological functions that characterize humans are generated by combined interactions among

genes rather than a specific gene being responsible for a specific function. The genome and transcriptome consist entirely of deoxyribonucleic acid (DNA) and ribonucleic acids (RNA). Their uniform chemical properties have enabled efficient, low-cost, and high-throughput methods for amplification, synthesis, sequencing, and highly multiplexed analysis.

The genome represents a rich source of information about our pathophysiology. Genome analyses provide information about structural DNA changes and thus the probability of developing a condition. These analyses do not, however, provide information about whether and when a condition will manifest. Many diseases are caused by genetic mutations, and many more manifest as a genetic predisposition. More than 3000 gene mutations (www.omim.org/) have now been identified that are associated with more than 5000 human phenotypes that cause or predispose to diseases. These numbers suggest that many diseases are caused by mutations in single genes and that many more have an inheritable genetic component. The Human Genome Project (HGP) was an international research effort originated in 1990 that culminated in the identification and public release of the completed sequence of the human genome in April 2003. In the HGP, the genome was cloned first and then larger clones were divided into shorter pieces and

sequenced. The HGP has revealed approximately 20,500 human genes. They are contained in more than 2.85 billion nucleotides covering more than 99% of the euchromatin (i.e., gene-containing DNA). Initial genome approaches were applied to the diagnosis of congenital birth defects and tumors. However, the introduction of next-generation DNA sequencing (NGS) has revolutionized biomedical research and promises to be of great value for the diagnosis of infectious diseases.¹¹⁸

Basics of the Genomics Approach

We now have a broad arsenal of techniques for genome analysis at our disposal, which allow the detection of gross abnormalities down to single nucleotide changes. These tools are increasingly being used for

FIG. 3.1 Each pathogen induces a specific response in the host that can be measured. An alternative approach to the pathogen-detection strategy is based on a comprehensive analysis of the host response to the infection caused by different pathogens.

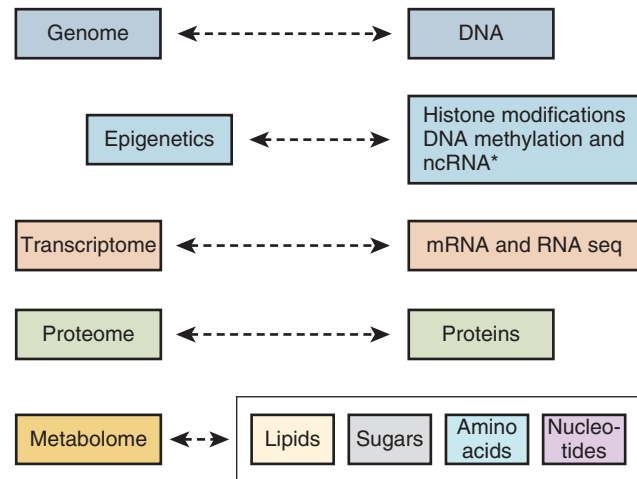

FIG. 3.2 Types of -omics approaches. *Genomics* provides information about structural DNA changes and thus the probability of developing a condition; *epigenetics* describes the chromatin modifications that are caused by external or environmental factors and stably alter gene expression without changing the DNA; *transcriptomic* approaches study the overexpression or underexpression of genes (mRNA expression profiles) in a qualitative and quantitative manner in response to the infection; and *metabolomics* and *proteomic methodology* analyze the structure, function, and interaction of posttranslational metabolites produced by a particular gene.

FIG. 3.3 Omics approaches are complementary. The information provided by the -omics technologies is complementary, and their use for diagnostic, pathogenesis, or prognostic purposes is mainly limited by the available technology and complexity of the analyses. ME, Methyl group.

clinical diagnostics. Within a few years the study of the human genome has dramatically changed and greatly improved, moving from the identification of abnormalities based on the morphology and number of chromosomes (karyotype) to the newly developed sequencing instruments that are able to generate millions of short sequences per run (NGS).

Karyotyping was the first method used for the identification of chromosomal abnormalities. Developed in the early 1960s, it is based on the identification of the banding pattern characteristic for each chromosome visible through the light microscope. Although it only reveals crude information, such as number, shapes, and gross alterations of general chromosomal architecture, it remains a mainstay of clinical genetic analysis. Trisomy 21 and chronic myelogenous leukemia were originally identified using this technique.^{8,12}

Comparative genome hybridization is a cytogenetic method focused on copy number variations relative to the number of chromosomes (ploidy) in the DNA. In comparative genome hybridization, the genomes of interest, which are usually a disease genome set against a normal control genome, are labeled with different fluorescent dyes and compared. Using different colored fluorescent labels, several genes can be stained simultaneously. When the technology was developed the fluorescently labeled DNAs were hybridized to a spread of normal chromosomes and evaluated by quantitative image analysis, which was able to detect chromosome regional gains or losses with greater accuracy than conventional karyotyping.^{59,105} Further improvements in resolution have been achieved using microarray-based comparative genome hybridization methods in which the probe DNA can be amplified by PCR, thus only minute amounts of starting material are required.^{62,166} The labeled DNA is then hybridized to an array that can contain millions of oligonucleotides included on chips the size of a microscope slide, achieving very high resolution. Comparative genome hybridization techniques are used in prenatal screening for the detection of chromosomal defects. However, they do not provide information about balanced changes, such as inversions or balanced translocations, because they do not change the copy number and hybridization intensity. To circumvent this issue, if the gene of interest is known, the respective recombinant DNA can be labeled and used as a probe on chromosome spreads. This method, called fluorescence in situ hybridization (FISH), can detect gene amplifications, deletions, and chromosomal translocations.

DNA sequencing is the ability to identify individual genes by determining the precise order of the four nucleotides (adenine, guanine, cytosine, and thymine) within a molecule of DNA. The rapid speed of sequencing attained with modern DNA sequencing technology has been instrumental in the sequencing of the complete human genome, which culminated in 2003. Over the years different techniques have been used for DNA sequencing. Initially the Maxam-Gilbert sequencing method used chemicals to cleave specific bases. This methodology was quickly discouraged due to its complexity and the use of radioactive labeling.¹³⁹ In parallel, Sanger used small concentrations of radio- or fluorescently labeled dideoxynucleoside triphosphate (dNTP) molecules and developed a relatively reliable and less cumbersome method called chain termination. Sanger's method was soon automated and was the method used in the first generation of DNA sequencers.²⁰⁰ The rapid development of novel technologies, such as NGS, has revolutionized this field. There are several NGS methods using different approaches to read DNA sequences. All these novel methods share the principle of conducting millions to billions of parallel sequencing reactions in microscopic compartments on arrays or nanobeads. Among others, DNA sequencing is used for genome-wide association studies (GWAS) using single nucleotide polymorphisms (SNPs) as high-resolution markers. SNPs are variations among individuals at a single position in a DNA sequence.⁸⁸ If more than 1% of a population does not carry the same nucleotide at a specific position in the DNA sequence, then this variation can be classified as an SNP. SNPs are associated with both genes and noncoding regions of DNA and represent the most common type of genetic variation among individuals. In 2012, more than 180 million SNPs were known. SNPs are useful to identify and assess disease risk, but it is not uncommon that they are found to have no impact on the phenotype (silent mutations).²²¹ Silent mutations, along with the need for extremely large cohorts of patients and for reproducibility of the studies, are among the main limitations of GWAS.

Genomics in Infectious Diseases

By 1950, using malaria as a prototype disease, the concept that genetic diversity within the host may influence the outcome of infection became apparent. In the clinical setting, the majority of infectious diseases are characterized by variation in both the disease pattern and severity, even during epidemics, thus highlighting the important role of host response on clinical manifestations and disease outcomes. Different inherited conditions, such as chronic granulomatous disease or interferon- γ receptor immunodeficiency, predispose to infectious diseases, and those conditions will be reviewed in another chapter. A number of SNPs in human leukocyte antigen (HLA) and non-major histocompatibility complex (MHC) have been found in response to a variety of bacterial and viral infections and have been associated with disease susceptibility, progression, or response to treatment. Table 3.1 illustrates examples of SNPs associated with a variety of uncommon and common viral or bacterial infections.* The main limitation of GWAS is that the same SNP can be protective or influence disease progression depending on the population and on the environment, making reproducibility of studies challenging.²⁵¹

EPIGENETICS

In 1957, Waddington developed the idea that some heritable traits are not reflected by changes in the DNA, and this change process is now known as epigenetics. Epigenetics describe a number of chromatin modifications (phenotypic trait variations) that are caused by external or environmental factors and stably alter gene expression without changing the sequence of the DNA.¹⁴ Thus epigenetics is able to alter the phenotype of a cell without changing the genotype and supports the idea that changes in gene expression derived from long-term exposure to a certain insult are imprinted, become independent of the activating stimulus, and persist even in its absence.¹⁹ Epigenetics include the study of DNA methylation as well as a variety of more transient histone modifications (such as acetylation, methylation, or phosphorylation) along with the influence of SUMOylation (the addition of small ubiquitin-like modifiers [SUMOs]), ubiquitination, adenosine diphosphate (ADP) ribosylation, and microRNA. Although the epigenome is more variable than the genome, it may hold greater information on an individual basis, which will be useful for the application of personalized medicine.

Basics of the Epigenetics Approach

The methodology used to identify changes in DNA methylation are similar to that applied in genomics and include DNA sequencing of the treated versus untreated DNA, hybridization techniques, or array-based methods. These techniques may miss some incomplete modifications; however, new NGS methods that are able to detect DNA methylation directly look promising and will accelerate the field. The main epigenetic changes include histone modifications (such as acetylation and methylation that affect chromatin structure) and DNA methylation. It is important to note that although DNA methylation silences gene expression, histone modifications can enhance or suppress gene transcription. DNA methylation patterns have been associated with diseases and can be heritable by a poorly understood process called genomic imprinting. In addition, epigenetics includes the understanding of noncoding RNAs (ncRNAs), which are transcribed molecules that do not translate into proteins. In regard to epigenetic modifications, one of the long ncRNAs more recently discovered are small ncRNAs or microRNAs (miRs).¹⁹⁵ miRNAs are highly conserved, small noncoding RNAs that target mRNA molecules and inhibit their translation. miRNA exist intra- and extracellularly, including in blood or serum, and are resistant to boiling or repeated freezing-thawing, thus promising to be useful biomarkers in the clinical setting.⁷⁴

Epigenetics in Infectious Diseases

There is growing evidence that histone modifications and chromatin remodeling regulate gene expression, including host immune responses,

CCR, Chemokine receptor; CFH, complement factor H; CFHR3, CFH-related protein 3; CXCL12, chemokine; EPHX1, epoxide hydrolase 1, microsomal; FUT2, fucosyltransferase 2; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; HSV, herpes simplex virus; IFN, interferon; IL-1, interleukin-1 (gene); IL-23R, interleukin-23 receptor (gene); IL-28B, interleukin-28B; LRRK2, leucine-rich repeat kinase 2 (LRRK2); LTA, lymphotoxin alpha; Mal, myeloid differentiation primary response gene 88 (MyD88) adaptor-like protein; MBL, mannose-binding lectin; MICB, major histocompatibility complex class I polypeptide-related sequence B; NOD2, nucleotide-binding oligomerization domain containing 2; PLCE1, phospholipase C, epsilon 1; PTPN22, protein tyrosine phosphatase nonreceptor, type 22; RAB32, member RAS oncogene family; RIPK2, receptor-interacting serine-threonine protein kinase 2; RSV, respiratory syncytial virus; TIRAP, Toll-interleukin-1 receptor (TIR) domain adaptor protein; TLR1, Toll-like receptor 1 gene; TNFSF15, tumor necrosis factor (ligand) superfamily member 15; VDR, vitamin D receptor.

and thus represent key targets for pathogen manipulation during infection.⁸⁰ A variety of viral and bacterial effectors have been identified that enable a pathogen's survival by either mimicking or inhibiting host cellular machinery. Mitogen-activated protein kinase (MAPK), interferon (IFN), or transcription factor NF- κ B signaling pathways, among others, are common targets of pathogen-induced posttranslational modifications on histones and chromatin-associated proteins.^{91,192}

In Vitro Studies

The majority of the initial epigenetics work associated with miRNA in relation to infections was performed in vitro and mostly included viral-induced diseases. The goal of these studies was to gain a better understanding of the mechanisms of diseases or to identify markers associated with organ-specific syndromes and/or severity associated with specific pathogens. Using a laryngeal epithelial cell model of enterovirus 71, Cui and colleagues identified 64 miRNAs that target a number of genes associated with neurologic and immune responses relevant to the pathogenesis of the disease.⁴³ Similarly, using primary human alveolar and bronchial epithelial cells infected with influenza A virus, Buggele and colleagues identified six miRNAs targeting a number of mRNAs, including receptor-associated kinase 1 (IRAK1) or MAPK3 and other components of the innate immune response to infection.²⁵ Another provocative study showed that influenza H3N2 uses one of its nonstructural (NS) proteins to circumvent immune responses. Investigators showed that the influenza NS1 protein had a histone-like sequence (ARTK-histone mimic) that inhibited the host transcription elongation factor (hPAF1), selectively suppressing the host cell's production of antiviral proteins.¹³⁵ Within alveolar macrophages, Pennini and colleagues showed that *Mycobacterium tuberculosis* (TB) inhibited the expression of several interferon- γ -induced genes through histone acetylation, which appears to be a ubiquitous mechanism used by intracellular pathogens. This mechanism may help explain the protracted course and persistence of TB in some patients.¹⁸⁰ These studies, although descriptive, are examples of how pathogens can directly induce epigenetic changes in the host. As a diagnostic tool, a study conducted in mice infected with either *Escherichia coli*, a gram-negative bacterium, or *S. aureus*, a gram-positive bacterium, identified three circulating miRNAs predictive of gram-positive bacterial infections.¹⁸⁸

In Vivo Studies

miRNA expression is a novel addition to the -omics arsenal to evaluate host responses to viral and bacterial infections. A small study in patients with dengue identified in blood samples two panels of miRNAs, one composed of 12 miRNAs and specific to dengue and another formed of 14 miRNAs common in dengue and influenza infection.²¹⁶ Another study was conducted with serum samples from children with hand-foot-and-mouth disease caused by EV-71 or Coxsackie virus 16 and included healthy controls and other infections including TB, pertussis, varicella zoster (VZV), or mumps.⁴⁴ Investigators found six miRNAs that discriminated children with EV-71 infection versus healthy controls with greater than 90% accuracy. However, only 2 of the 6 miRNAs identified were also found in their in vitro model. This emphasizes the need to perform studies in target populations because several factors, such as disease severity, age, or other parameters, may provide discordant results. A small study conducted in infants with respiratory syncytial virus (RSV) identified a distinct profile of immune-associated miRNA in respiratory samples from patients with mild or severe disease.⁹³ Although promising, these results will need to be validated in larger patient populations. Different studies have measured miRNA profiles in whole blood, peripheral blood mononuclear cells (PBMCs), or serum from patients infected with various strains of influenza A, including H1N1/H3N2, H7N9, or 2009 H1N1.^{209,217,250} However, results could not be validated in other studies, suggesting that there may be methodologic differences that must be addressed.²⁴³ In regard to bacterial pathogens, the majority of epigenetic studies have focused on TB or sepsis. A study that analyzed the sputum of patients with active TB versus controls found 95 miRNAs that were differentially expressed and were subsequently validated by quantitative reverse transcription PCR (RT-qPCR).²³⁸ Other studies conducted in adult and pediatric patients, with and without HIV, found a number of whole blood miRNAs in CD4⁺ T cells or sera that were differentially expressed in active versus latent TB or controls and had a specific role in T-cell immunity against TB.^{68,108,151,184} In regard to sepsis, serum miRNAs have been used mostly as a prognostic rather than diagnostic marker in critically ill patients with negligible or no overlapping findings among studies, which may be attributed to the different levels of disease and/or the patient populations included.^{131,194,213,230} Studies using miRNAs as a diagnostic tool for more common bacteria

are ongoing. Nevertheless the value of miRNAs for the diagnosis of bacterial and viral infections, especially in patients with pneumonia, will be evident when studies are conducted and validated in the main target populations.

TRANSCRIPTOMICS

Major technological breakthroughs have also occurred in the field of transcriptomics, thus creating a unique opportunity for the study of humans in health and disease where inherent heterogeneity dictates that large collections of samples need to be analyzed. Among the high-throughput molecular profiling technologies available today, transcriptomic approaches are the most scalable, have the most breadth and robustness, and therefore appear to be best suited for the study of human populations. The transcriptome represents the complement of RNAs (messenger RNA) that are transcribed from the genome. Genes encode the information to make proteins, and RNA is the messenger that transports that information (hence the name mRNA). The transcription of a gene yields an average of 4 to 6 mRNA variants, which are translated into different proteins. The translation of mRNAs into proteins is highly regulated. Protein-coding genes only constitute 1% to 2% of the human genome sequence; however, more than 80% of the genome can be transcribed. Thus the largest part of the transcriptome consists

of noncoding RNAs that fulfill important structural and regulatory functions, including gene transcription, mRNA processing and stability, and protein translation. One type of noncoding RNAs is the so-called small interfering (si)RNAs, which were discovered in 2006.²²⁴ siRNAs are part of an enzyme complex that targets and cleaves mRNAs with high specificity. These types of RNAs have become a powerful tool to downregulate (or silence) the expression of selected mRNAs with high specificity and efficiency.

Different classes of pathogens trigger specific pattern-recognition receptors (PRRs) differentially expressed on peripheral blood leukocytes.^{23,113,112} Blood represents both a reservoir and a migration compartment for these immune cells that become educated and implement their function by circulating between central and peripheral lymphoid organs and migrating to and from the site of infection via blood. Therefore blood leukocytes constitute an accessible source of clinically relevant information, and a comprehensive molecular phenotype of these cells can be obtained using gene expression microarrays.³³ Because they provide a comprehensive assessment of all immune-related cells and pathways, genomic studies are well suited to study the host-pathogen interaction (Fig. 3.4). In fact, studies in children and adults with acute infections have shown that different classes of pathogens induce distinct gene expression profiles that can be identified by analyses of blood leukocytes (Fig. 3.5).^{15,32,34,104,141,170,186,242}

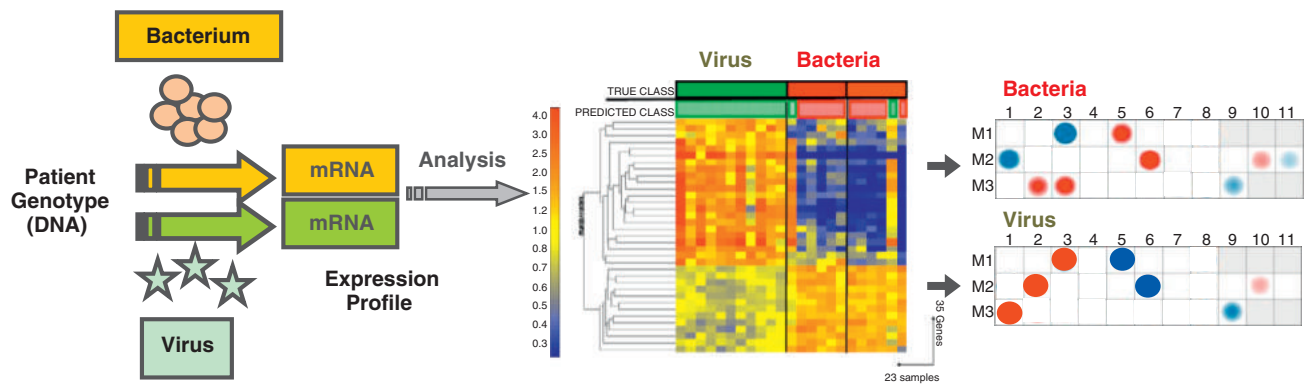

FIG. 3.4 Viral versus bacterial host responses. Microarray technology can measure the differences in gene expression patterns present in blood immune cells as induced by various types of infectious agents (viruses vs. bacteria) with a high level of specificity.

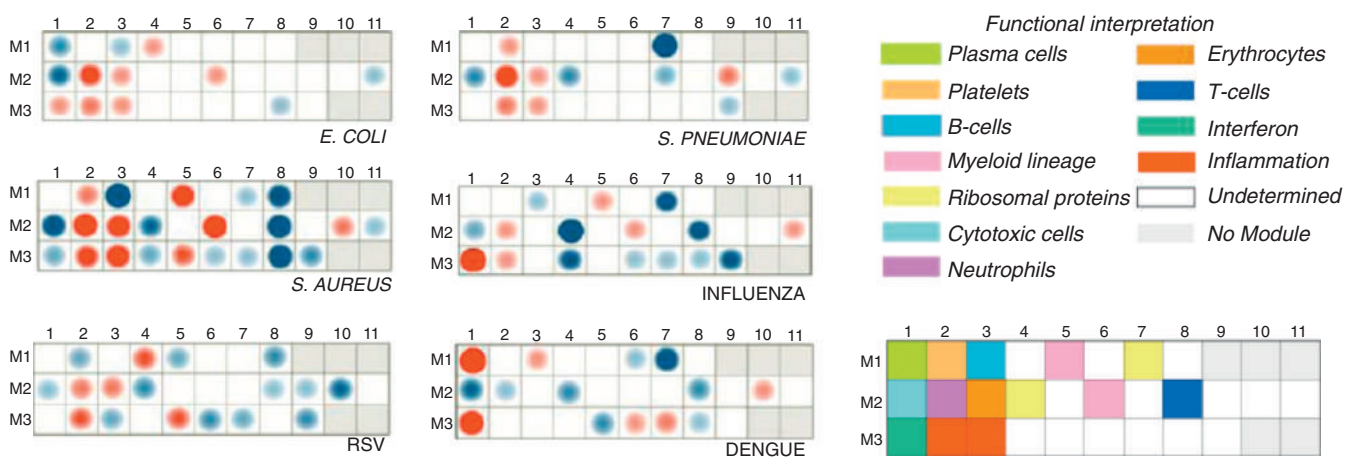

FIG. 3.5 Infectious disease fingerprints. Studies in children and adults with acute infections have shown that different classes of pathogens induce distinct gene expression profiles that can be identified by analyses of blood leukocytes. Expression levels were compared between patients and appropriately matched healthy controls on a module-by-module basis. The spots represent the percentage of significantly overexpressed (red) or underexpressed (blue) transcripts within a module (i.e., a set of coordinately expressed gene). Blank spots indicate that there are no differences in the genes included in that module between patients and healthy controls. This information is displayed on a grid, with the coordinates corresponding to one of 28 module IDs (e.g., module M3.1 is at the intersection of the third row and first column). Each pathogen induces an easily identifiable disease-specific biosignature. RSV, Respiratory syncytial virus.

Basics of the Transcriptomics Approach

Microarray Analyses

Microarray methods for studying global mRNA expression profiles are now well established. Microarray gene chips contain several million DNA spots arranged on a small slide in a predefined order. They allow a relative quantitation of changes in transcript abundance among different conditions. Modern arrays use unique sequences of synthetic oligonucleotides to avoid ambiguity in identifying specific RNA transcripts, and several oligonucleotides are used per gene to improve accuracy. The newer high-density arrays are able to scan the transcription of all human genes map exon content, and splice variants of mRNAs, including noncoding RNAs (such as siRNAs and miRNAs). Briefly, RNA derived from the cells or tissue analyzed is copied first to complementary cDNA using a reverse transcriptase that can synthesize DNA from RNA templates. cDNA is transcribed back into cRNA, which is labeled with fluorescent tags, such as biotin, to improve detection. cRNA is preferred to cDNA because it hybridizes more strongly to the array oligonucleotides. After hybridization, the microarray chip is scanned and the hybridization intensities are compared using different statistical software. Thanks to a common convention for reporting microarray experiments called Minimal Information for the Annotation of Microarray Experiments (MIAME), gene array databases that have been published are publicly available free of charge and represent a valuable source for further analysis in which microarray results from different experiments can be compared. Gene array analysis is already being used for clinical applications.

RNA Seq

Transcriptome analysis can also be performed by direct sequencing once RNAs have been converted to cDNAs. The advances in rapid and cheap DNA sequencing methods permit every transcript to be sequenced multiple times. These “deep sequencing” methods not only unambiguously identify the transcripts and splice forms but also allow the direct counting of transcripts over the whole dynamic range of RNA expression, resulting in absolute transcript numbers rather than relative comparisons. Thus the sequencing methods, called RNA seq, are quickly becoming attractive alternatives to array-based transcriptomic methods.²²⁸ Studies using RNA seq to characterize different infections are ongoing. As examples, two studies in mice, one in a model of *Staphylococcus aureus* infection²¹ and the second one in a model of H5N8 avian influenza virus,¹⁷² found transcripts associated with proinflammatory and anti-inflammatory mediators, chemotaxis, cell signaling, keratins, and TH1/TH17 cytokines.

Use of Transcriptomics in Infectious Diseases

Of all the -omics technologies, transcriptomics is probably the most popular, affordable, and easiest to implement approach because it allows measuring transcript abundance in a sample on a genome-wide scale using a single assay. Several studies have been conducted over the years, initially in vitro and subsequently in samples (usually PBMCs or whole blood) from patients with a variety of infectious diseases.

In Vitro Studies

The initial studies supporting the hypothesis that pathogen-specific gene expression profiles can be measured in immune cells were derived from in vitro studies. The comparative analysis of a compendium of host-pathogen microarray datasets identified both a common host transcriptional response to infection and a pathogen-specific signature.^{20,35,94,100} Upon activation, Toll-like receptors (TLRs) trigger signaling pathways that share common components while retaining unique characteristics, accounting in part for the specificity of transcriptional responses.²¹⁴ In fact, in vitro microarray studies have shown the ability of herpes simplex virus (HSV), West Nile virus, pseudorabies virus, hepatitis C viruses (HCV), VZV, and rhinovirus to limit the ability of the host to develop effective antiviral responses by a variety of mechanisms.^{90,185} However, the vast body of in vitro experimental data accumulated over the years suggests that hosts can mount pathogen-specific transcriptional responses to infections.

In Vivo Human Studies

Initial studies tested the hypothesis that leukocytes isolated from peripheral blood of patients with acute infections carry unique transcriptional signatures, which would in turn permit pathogen discrimination and classification. In those initial studies, gene expression patterns derived from PBMCs of pediatric patients hospitalized with acute infections showed that there are pathogen-specific signatures that can be measured in the blood, and these distinguished children with influenza A from *S. aureus*, *Streptococcus pneumoniae*, and *E. coli* acute infections with greater than 95% accuracy.¹⁸⁶ Analysis of PBMC samples requires processing in real time, which has limitations from a practical clinical application if there are large numbers of patients. In addition, PBMC samples do not include neutrophils, which is a relevant cell population for the pathogenesis of bacterial and viral infections. For these reasons, in recent years, there has been a shift toward whole blood samples to study transcriptional profiles in the clinical setting. Indeed whole blood signatures for several other infections have also been described from infected subjects including malaria, dengue, salmonella, melioidosis, TB, RSV, influenza virus (including the pandemic H1N1/09), rhinovirus, adenovirus, human T-cell lymphotropic virus (HTLV-1), HIV, and neonatal sepsis (Table 3.2).*

A study performed in adult volunteers experimentally infected with RSV, rhinovirus, or influenza A identified an “acute respiratory viral signature” that was independently validated using a previously published dataset of pediatric patients with pneumonia.¹⁸⁶ Despite the technical challenges involved in such analysis and the differences in the patient populations analyzed (children naturally infected vs. adults with experimental infection), the identified “viral signature” classified pediatric patients with influenza from age-matched healthy controls with 100% accuracy.²⁴² This is a critical observation that confirms the reproducibility and potential value of blood transcriptome analysis to study host immune responses to respiratory viruses in the clinical setting. Additional studies will be necessary to evaluate this approach in other relevant clinical situations where the application of this methodology has the potential to transform the standard of care. In this regard, two studies have already shown the utility of host gene expression profiles as a diagnostic tool when effective treatment depends on rapid identification of the infectious agent or even the need for treatment. In the first study, also using adult volunteers experimentally infected with influenza A H1N1 or H3N2,²⁴² the authors found a blood RNA signature that was detectable more than 24 hours before the peak of clinical symptoms.²³⁵ Subsequently, the same group of investigators used the transcriptome profiles derived from the experimental influenza signature²⁴² to develop a targeted host-based RT-PCR low-density array assay. This assay was applied to adult patients presenting with fever to the emergency department (ED) and differentiated viral versus bacterial infections with 89% sensitivity and 94% specificity,²⁴¹ demonstrating that gene expression profiles identified by microarray analyses can be successfully applied to custom-made platforms with the potential for a fast, point-of-care patient diagnosis and classification. It is remarkable that although in the majority of studies patient samples were collected at different time points after pathogen exposure and disease onset, robust and pathogen-specific biosignatures have been derived and validated in independent cohorts of patients in completely different settings.

Areas for Improved Diagnosis in Pediatrics

Lower Respiratory Tract Infections (LRTI)/Pneumonia

Acute LRTI/community-acquired pneumonia (CAP) represent the leading cause of hospitalization in the United States and is the main cause of death worldwide in children less than 5 years of age.^{79,119,125,128} In industrialized countries, CAP has an annual incidence of 36 to 40 per 1000 children below the age of 5 years and 11 to 16 per 1000 in children 5 to 14 years of age.¹⁰³ In the United States it is second only to injuries as the most common reason for hospitalization in children less than 18 years of age.¹⁶⁰ In current clinical practice, establishing the precise etiologic diagnosis of pneumonia, or even simply discriminating viral from bacterial respiratory infections, remains

challenging. Unfortunately the pressure to achieve a rapid resolution of symptoms has commonly led medical practitioners to take an overcautious approach and treat many patients unnecessarily with antibiotics. Recent studies have provided an initial proof of concept of how application of blood gene expression profiles could represent an alternative approach for the diagnosis of viral and bacterial LRTI.^{15,87,104,141,173,242} Two landmark studies published in 2013 have shown the potential of transcriptome analysis for diagnosis and patient classification in two completely different clinical situations in which traditional tools have been demonstrated as insufficient: TB and RSV infections.^{104,141}

TB remains a major diagnostic challenge, especially in the developing world where the prevalence of HIV is high. A study conducted in Africa showed the value of whole blood transcriptome analysis for the diagnosis

of TB in a large cohort of HIV-infected and uninfected patients. From the expression data, the authors developed a disease risk score that discriminated with high sensitivity and specificity (>90%) between patients with active TB and those with an alternative diagnosis but who presented initially with suspected TB and even from patients with latent TB infection.¹⁰⁴ In young children, respiratory viral infections and specifically RSV represent the most common cause of LRTI leading to hospitalization worldwide. In the clinical setting it is impossible to predict, based on the physical examination and available diagnostic tools, which patients with RSV infection will progress to severe disease requiring hospitalization and which patients can be discharged home safely. Hence there is a clear need to better understand the immune response to RSV and how it relates to disease pathogenesis, progression, and severity. A recent study conducted in the United States analyzed a

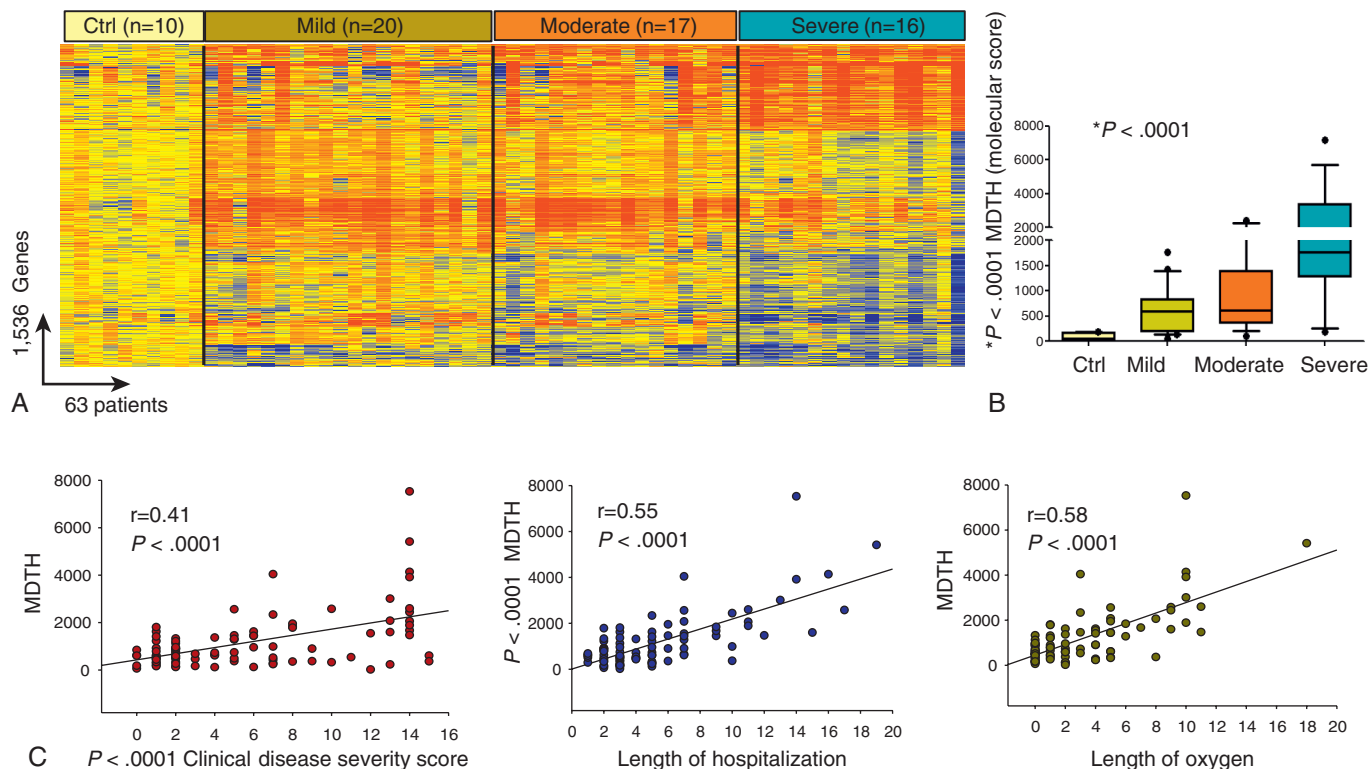

FIG. 3.6 (A) A molecular score correlates with disease severity and clinical outcomes in children. Hierarchical clustering of genes differentially expressed (Kruskal-Wallis $P < .01$, Benjamin-Hochberg multiple test correction) between infants with respiratory syncytial virus (RSV) LRTI and 10 healthy matched controls demonstrated a higher proportion of underexpressed genes in children with severe RSV ($n = 16$) that gradually declined in patients with moderate ($n = 17$) and mild RSV disease ($n = 20$). Each column represents a patient's sample and each row a transcript. (B) Using those 1536 transcripts, molecular distance to health (MDTH) scores were calculated and were higher in children with severe disease than in children with mild or moderate disease ($P < .001$). (C) The genomic MDTH score significantly correlated with the clinical disease severity score, the total length of hospitalization, and the duration of supplemental O_2 in the overall RSV cohort ($n = 91$).

cohort of 220 children younger than 2 years of age who were hospitalized with acute RSV, rhinovirus, and influenza A LRTI and showed that blood RNA profiles differentiated these three viral infections with 95% accuracy.¹⁴¹ In addition, and as previously suggested,^{24,94} RSV infection induced overexpression of interferon and neutrophil genes and suppression of B- and T-cell genes, which persisted beyond the acute disease and was greatly impaired in infants of less than 6 months of age. These results may explain in part the lack of protective antibody responses observed after acute RSV infection. Moreover, the authors identified a genomic score that significantly correlated with outcomes of care (Fig. 3.6). Altogether these studies demonstrate that large amount of microarray data can be translated into a biologically meaningful context that can be correlated with disease severity and applied in the relevant clinical setting to accurately classify patients. It is remarkable that blood signatures can achieve such accuracy for the diagnosis of respiratory pathogens that are thought to be mostly confined to the respiratory tract. From a practical perspective, in the majority of the clinical situations, obtaining a blood sample is more feasible than obtaining infected tissue.

Febrile Infant Without a Source

The evaluation of febrile infants, and especially those less than 2 months of age, who present to the ED continues to represent a major challenge for clinicians. Although viral infections are a common cause of fever with no apparent source in young infants, many children receive antibiotics unnecessarily due to the risk of serious bacterial infections. This is mainly due to the deceiving clinical appearance of the infant, coupled with the poor sensitivity of our current diagnostic tools. A study

conducted in children 2 to 36 months of age presenting with fever to the ED showed that transcriptional profiles clearly distinguished between children with bacterial and viral infections and classified those patients with better accuracy than traditional white blood cell counts (WBC). Moreover gene expression profiles clearly differentiated symptomatic febrile from nonsymptomatic control children infected with the same virus (HHV-6 or adenovirus).⁹⁰ Currently an ongoing large multicenter study is being conducted by the Pediatric Emergency Care and Research Network (PECARN) in the United States to evaluate the application of transcriptional profiles for diagnosis of young febrile infants of less than 2 months of age in the ED.^{133,252}

Differentiating Infection Versus Colonization

Whole blood RNA expression profiles represent much more than an expensive traditional WBC and have significantly superior capacity at discriminating bacterial from viral infections.^{90,167,186} The readout is a combined representation of the number and cell types and the activation or suppression of all these cell types in peripheral blood. A recent study was conducted to evaluate the ability of host transcriptional profiling to differentiate between symptomatic rhinovirus infection and incidental detection of rhinovirus in a large cohort of children less than 2 years of age. Investigators found that symptomatic rhinovirus infection induced a robust and reproducible transcriptional signature, whereas identification of rhinovirus in asymptomatic children was not associated with significant systemic transcriptional immune responses.⁸³ These findings also demonstrate the applicability of these tools in the clinical setting where gene expression profiles can help to determine the clinical significance of detecting viral nucleic acid in individual patients.

PROTEOMICS

Proteomics is a relatively young discipline that emerged originally to complement transcriptomic studies.⁴⁰ Genomic data provide information about DNA or RNA transcription (mRNA) and thus represent the intermediate step between a given gene and its cognate protein. In contrast, the main principle underlying the use of proteomics is that proteins are the functional molecules ultimately responsible for controlling most cellular functions.¹²³ The main interest in proteomics is due in part to the prospects that a proteomic-based approach to disease investigation will overcome the limitations of other approaches.¹⁸¹ The term *proteome* was coined by Wilkins in 1994, and it refers to the entire set of proteins expressed by a genome, cell, tissue, or organism at a certain time. Proteomics refers to the systematic analyses of these proteins, particularly their structures and functions.¹⁷⁷ Like genomics, proteomics is used to identify expression patterns at a specific time during the course of the disease in response to a specific stimulus. In the case of the proteome, the 22 most abundant proteins, including albumin and the immunoglobulins, account for 99% of the total proteome mass; however, many of the interesting molecules relevant to human disease occur in low abundance (in the nanomolar, picomolar, or even femtomolar range, such as tumor necrosis factor- α [TNF- α]).³ In 2012, the Human Protein Atlas, a major resource for proteome analyses, comprised more than 14,000 proteins (approximately 70% of gene products) with ongoing efforts to include protein variants and posttranslational modifications.

Basics of the Proteomics Approach

Proteomics relies on a multistep approach including the separation of complex mixtures of proteins or peptides, quantification of protein abundance, and identification of the proteins. Proteome profiling technologies are evolving in a manner that emphasizes the need for both sensitivity and throughput. Within the past decade, mass spectrometry (MS)-based proteomics has emerged as a useful tool to better understand host-pathogen interactions,²³⁷ allowing the identification and quantitation of large numbers of proteins with great accuracy. The measurement of the proteome and posttranslationally modified proteome dynamics using MS results in a wide array of information that can be linked to the patient's clinical picture, such as significant changes in protein expression, protein abundance, the modification status, or the functional significance of key proteins.¹⁸⁹ Different strategies have been developed over the years to define and quantitate proteome profiles.

Protein Separation Strategies

Separation strategies are driven by the need to reduce complexity (i.e., the number of proteins being analyzed) while retaining as much information as possible on the functional context of the protein. In its early stages, proteomics relied on high-resolution, two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) to separate, identify, and quantitate single proteins present in a sample.¹⁶³ A cocktail was used to solubilize the protein contents of a biological fluid or tissue, followed by separation of the lysate protein content using two-dimensional gels. However, 2D-PAGE required that protein spots needed to be selected individually from the gels for subsequent identification by MS, allowing a limited display of relatively abundant proteins. This technology has been replaced by two-dimensional fluorescence difference gel electrophoresis (2D-DIGE) and liquid chromatography (LC), which allows multiple samples to be co-separated and can be directly coupled to MS.²¹⁸

Nonprotein Separation Strategies

To address the different features of proteins that can be altered during the disease process, protein microarray strategies have been developed. Ideally protein chips should be able to measure both the protein concentrations in biological samples as well as the protein interactions with other molecules, including other proteins, antibodies, or small ligands. Nevertheless, a major limitation of this approach is that proteins undergo numerous posttranslational modifications that may be crucial to their functions and are generally not captured using these tools.⁸² Recent technological advances have made MS an indispensable technique for

proteomic analyses.¹⁷⁶ MS is a technique used to identify the amount and types of molecules in a sample by measuring their molecular mass. There are many different types of mass spectrometers available, but the underlying principles of MS are relatively standard: ionization source, mass analyzer, and ion detector.⁸¹ The first step in the process is to generate charged molecules, or ions, from the molecules in the sample. Molecules are then converted into gas-phase ions and separated by the mass analyzer, which uses electric or magnetic fields or time of flight (TOF) to separate ions,²⁶ and the matrix-assisted laser desorption/ionization (MALDI). The development of MALDI-TOF as a soft ionization technique suitable for proteins and peptides that tend to be fragile has revolutionized the applications of MS for proteomics, clinical microbiology, and biology in general.^{50,60,210} Tandem MS instruments, such as the MALDI quadrupole ([Q]-TOF) have been recently developed to allow fast protein identification through database sequences.²⁴⁰ For data mining and automation, which enables the accurate and fast diagnosis of human diseases, a novel approach combined two powerful techniques of chromatography and MS, and surface-enhanced laser desorption/ionization (SELDI) was developed.⁹⁶ One of the key features of SELDI-TOF MS is its ability to provide a rapid protein expression profile from a variety of clinical samples.

Proteomics in Infectious Diseases

Circulating host proteins represent an attractive alternative to monitor host responses to infection and can be used as point-of-care testing because of their fast turnaround time. Proteins that are routinely used to support the diagnosis of infections include CRP and PCT, which will be discussed separately.²⁰⁶ Microbial pathogens display host specificity through a complex network of molecular interactions that help with their survival and propagation. Proteomics-based approaches and posttranslational modification analysis through MS technologies can be efficiently applied to identify and quantitate large numbers of proteins with great accuracy and to gain insight into the molecular mechanisms involved in host-pathogen interactions.⁴¹ From a practical point of view, protein targets do not require amplification and are easily applicable to current clinical practice. An example is the rapid group A streptococcus test that relies on lateral flow immunochromatography. Thus despite the technological challenges, the potential to develop fast, simple, low-cost assays for infection diagnosis and prognosis is compelling; nevertheless, to derive meaningful conclusions using this tool, it is critical that the appropriate samples are used.

The use of proteomics in infectious diseases through MALDI-TOF MS has been mainly applied to identify causative pathogens in a time-efficient manner and to understand the mechanisms of diseases. A recent study showed that of 1660 bacterial isolates analyzed, MALDI-TOF correctly identified 95.4% of them: 84% were identified at the species level and 11.3% at the genus level. Importantly, once pathogens grew, the mean time required to identify one isolate was 6 minutes, thus significantly decreasing the cost of current methods of identification.^{102,175,204}

In Vitro Studies

To better understand the pathogenesis and mechanisms of viral infections, different studies have incorporated labeled amino acids into tissue culture for MS-based quantitative proteomics in vitro. This approach, also called stable isotope labeling with amino acids in cell culture (SILAC), in conjunction with LC-MS/MS has been applied to quantify changes in the nucleolar proteome of in vitro influenza A, RSV, and adenovirus infection, among others.^{116,155,248,249} Studies in different areas of infectious diseases have been conducted to discover the host-pathogen biomarkers that can help with diagnosis, assess clinical severity, and predict response to therapy. The main syndromes to which proteomics have been applied in vivo in a variety of biological fluids are lower respiratory tract infections/pneumonia including TB, hepatitis, HIV, and perinatal infections including chorioamnionitis or necrotizing enterocolitis (NEC).

Human Studies

As mentioned earlier, lower respiratory tract infections represent the global leading cause of death in children younger than 5 years.⁷⁵ Despite the frequency with which it is encountered, the diagnosis and

management of pediatric lower respiratory tract infections remain a significant challenge to practitioners. First, a specific etiology is not identified in many cases,^{56,103,110,144,153,225,236} making targeted therapy difficult. Additionally, the clinical features of lower respiratory tract infections are variable and overlap.^{130,137} In this field, proteomics has been used mainly to identify the causative pathogen and understand the mechanisms of disease.^{18,182} A limited number of studies have utilized proteomic host responses to assess disease severity and/or as a diagnostic tool to identify the causative agent. Surfactant protein A or D obtained from bronchoalveolar lavage and serum amyloid A protein have been identified as markers of lung damage in patients with a variety of respiratory diseases.^{9,239} Plasma proteomic profiles from adults experimentally infected with influenza A H3N2 virus were analyzed using LC-MS tools at baseline and at the disease peak. The authors found several thousand isotope groups per sample with almost 10% mapping to known proteins; of those, AGL2 (an acute phase reactant-like protein) was greatly correlated with symptomatic disease.²⁴³ A recent study conducted with 1000 participants, including pediatric and adult patients with a variety of infections, found that the combination of host proteins participating in viral and bacterial pathways had superior diagnostic accuracy to any of these proteins alone. In addition, the three-proteome signature (TNF-related apoptosis-inducing ligand [TRAIL], interferon γ -induced protein-10 [IP-10], and CRP) was superior to any clinical parameter used in the study.¹⁶⁸ The obvious next steps would be to apply this signature specifically to patients with lower respiratory tract infections to differentiate viral versus bacterial versus viral-bacterial pneumonia so appropriate management and targeted therapy can be promptly instituted.

Proteomics has also been applied to improve the diagnosis of TB. A study conducted in serum samples from 102 adult patients with culture-positive TB and 170 healthy controls found a proteomic fingerprint composed of four biomarkers (serum amyloid A protein, transthyretin, neopeptin, and CRP). This signature was able to predict the TB status in an independent cohort of 77 patients with 78% accuracy.¹ A more recent study performed in serum samples from 180 patients with active TB identified a different four-biomarker signature that was predictive of active TB versus controls also with about 80% accuracy. In addition, investigators found that patients with active TB had increased concentrations of fibrinogen and fibrinogen degradation products, which may also help to monitor response to therapy.¹²⁴

In recent years the prevalence of hepatocellular carcinoma (HCC) associated with both hepatitis B (HBV) and HCV has significantly increased.⁴⁹ The current biomarkers used for diagnosis (α -fetoprotein) lack the appropriate sensitivity, and, until recently, the gold standard for therapy included interferon and ribavirin, whose response was variable and hard to predict. HCC usually has a poor prognosis, due in part to the fact that the disease is often diagnosed in advanced stages. Thus the discovery of host-viral biomarkers to predict response to therapy and for early detection of HCC has become a priority.¹⁵⁷ A study conducted in serum from treatment-naïve HCV patients and validated in a new cohort of patients identified a three-metaprotein signature that was able to predict response to therapy with high accuracy (90% in the training cohort and 88% in the validation group). Of the 105 proteins identified with two or more peptides (a total of 3768 peptides), regression modeling found vitamin D binding protein, α -2 HS glycoprotein, and complement C5 to have the best predictive area under the receiver operator (ROC) characteristic curve.¹⁷⁴ Unbiased protein profiling of liver tissue has also been applied to identify pathways associated with the development of HCV-related fibrosis and HCC.^{54,122,158} A main limitation in these studies is the difficulty in obtaining samples and thus the inability to validate results.

HIV continues to affect millions of people worldwide and has caused more than 35 million fatalities. The virus is able to cross the blood-brain barrier, which may result in neurocognitive impairment and/or AIDS dementia. Using serum and cerebrospinal fluid (CSF), investigators have attempted to identify a proteomic fingerprint predictive of HIV-associated CNS disease, with contradictory results.^{13,117} Investigators have also used proteomic approaches to diagnose damage inflicted by the antenatal or postnatal exposure of the fetus to infection/inflammation.

Good examples are the studies performed by Buhimschi and colleagues in the field of chorioamnionitis; they analyzed proteomic fingerprints, including CRP and interleukin-6 (IL-6), in urine and amniotic fluid samples from pregnant women for the diagnosis of intraamniotic infections with promising results.^{27,26} Similarly, Sylvester and colleagues conducted a study in 85 premature infants with suspected NEC, 17 with sepsis, and 17 controls and applied proteomics in urine samples. They found and validated a seven-proteome signature that was diagnostic of NEC and help to identify neonates at risk of developing severe or surgical disease.²¹²

C-Reactive Protein

CRP is a pathogen-associated molecular pattern recognition protein of the pentraxin family synthesized by hepatocytes after IL-6 stimulation. It was first identified in 1930, when sera from patients with *Streptococcus pneumoniae* infection were found to have a protein that binds to the C-polysaccharide of the bacterial cell wall. CRP not only recognizes microbial polysaccharides but also necrotic cells, chromatin subunits, and small nuclear riboproteins, all of which are exposed at sites of tissue damage.²⁹ CRP bridges the gap between innate and adaptive immunity by activating the classical complement pathway and was recently found to bind cellular immunoglobulin Fc receptors as well.⁵⁸ CRP deficiency in humans has not been described. CRP induces the production of inflammatory cytokines and tissue factors and the shedding of the IL-6 receptor, all of which result in a complement-dependent increase in tissue damage.⁷⁷ Thus it is not surprising that CRP is elevated as part of the acute-phase response to inflammation or infection. After an acute inflammatory stimulus, CRP concentration increases rapidly and peaks at 2 to 3 days at levels that reflect the extent of tissue injury. If the stimulus has been removed, serum CRP levels drop rapidly, with a half-life of roughly 19 hours.²²⁷ Persistent elevations in CRP are seen in chronic inflammatory states such as pulmonary TB. Used along with ESR, these levels are useful markers to monitor disease activity but are not as useful for differential diagnosis. Overall the value of CRP appears to be inferior to other biomarkers. CRP has shown a sensitivity of about 70% and a specificity that varies between 65% and 90% for patients with bacterial lower respiratory tract infections.^{65,89} Nevertheless, as with other biomarkers, it needs to be interpreted in the appropriate clinical scenario.

Procalcitonin

PCT was discovered in the early 1960s as a peptide precursor of the hormone calcitonin. It is released by parenchymal cells (C-cells of the thyroid gland or neuroendocrine cells in the lung or intestine) in response to bacterial toxins; thus serum levels are elevated in patients with bacterial infections, whereas its production appears to be decreased in patients with viral infections. Multiple studies have shown that PCT is involved in the pathogenesis of infections and that it can be a useful diagnostic marker for bacterial infections such as bacterial pneumonia,¹⁰¹ serious bacterial infections in young children, septic shock, meningitis, or urinary tract infections.^{109,132,150,201} On the other hand serum PCT concentrations naturally fluctuate during the first 48 hours of life and require adjustments for the estimated gestational age of the premature newborn. Thus its value as a biomarker of early-onset sepsis appears less reliable.¹²⁷ In addition, PCT has been studied to facilitate the appropriate use of antibiotics. Two studies followed patients with lower respiratory tract infections/CAP in which clinicians were advised not to prescribe antimicrobials if patients had low PCT concentrations (<0.1 $\mu\text{g/L}$) but were encouraged to use them if PCT levels were greater than 0.25 $\mu\text{g/L}$.^{37,39} These and other studies, including a meta-analysis that used individual patient data from 4221 patients with acute respiratory infections included in 14 trials, showed that information about PCT resulted in lower rates of antibiotic exposure.²⁰² Although PCT has been shown to have greater specificity and sensitivity than CRP as a biomarker, it should not be used without evaluation of other clinical and laboratory data in clinical decision making because the cutoffs to determine the probability of bacterial infections vary depending of the type of infection and setting and because serum PCT concentration may be normal in patients with sepsis or increased in some individuals with no clinical symptoms.³⁸

METABOLOMICS

Metabolomics involves the rapid, high-throughput characterization of small metabolites. Similar to proteomics, it represents a promising approach to identify biomarkers of disease by defining metabolomics profiles. Metabolites are small chemical molecules including sugars, amino acids, or lipids that are present in a given biological sample. In 1971, it was postulated that metabolites in biologic fluids could be measured in a quantitative and qualitative manner, reflecting the functional status of those biologic systems. This approach was ultimately referred to as *metabonomics*, although today both the terms *metabonomics* and *metabolomics* are used.^{161,178} More recently focused analyses of specific metabolite families or subsets, such as lipids, have given rise to “lipidomics,” which is becoming a separate entity.¹¹⁵ Metabolomics focuses on identifying and quantifying both the steady-state as well as the dynamic changes of metabolites, providing information regarding the activity of enzymes that in turn are modulated by substrates, cofactors, and small molecules or proteins. Since the metabolome is closely tied to the genotype of an organism, its physiology, and its environment, metabolomics offers a unique opportunity to study genotype-phenotype as well as genotype-environment relationships. Using MS, Millington and colleagues found that by screening for fatty acids and organic and selected amino acids in neonates, certain inborn errors of metabolism could be diagnosed.⁶⁶ This was a seminal discovery and has served as the basis for future work in this field. Since then, the application of metabolomics to gain new insights into the mechanisms of diseases, improve diagnosis, and help with prognosis has significantly increased, and it is being used in a variety of health applications including pharmacology, toxicology, transplant monitoring, and infectious diseases.^{69,162,211}

In 2007, the Human Metabolome Project released the first draft of the human metabolome consisting of approximately 2900 endogenous or common metabolites that have certain specificities for given tissues or body fluids (309 metabolites in CSF, 1122 metabolites in serum, 458 metabolites in urine, and approximately 300 metabolites in other tissues/biofluids). Different tissues/biofluids have different functions and/or metabolic roles, and recent estimates suggest that the human metabolome includes approximately 5000 small molecules.²³⁴ A key limitation to metabolomics is the fact that the human metabolome is not yet well characterized.

Basics of the Metabolomic Approach

Analyses of the metabolome are complex because of its dynamic nature and also due to the fact that many metabolites give rise to different molecules that are partially formed from products derived of food, drugs, the gut microbiome, and even the environment. Compared with proteomic techniques, metabolomic technologies focus on smaller compounds, generally less than 2 kDa in size. Metabolites are usually easily separated from proteins by simple extraction techniques and precipitation and removal of the proteins. The methods most commonly used to analyze metabolites are similar to those used for proteomic analyses and include MS, often coupled to LC, and gas chromatography (GC) MS, as well as nuclear magnetic resonance (NMR) spectroscopy. Similar to proteomics, the approach used for metabolomic analyses can be performed in a targeted manner or using a pattern discovery approach, depending on the objective of the study.

For biomarker discovery, *metabolomic fingerprinting* is commonly used because it does not require a prior knowledge of the metabolite and has less inherent bias. Using this unbiased approach investigators confront a complex pattern of peaks, many of which are anonymous, and the molecular identities of the species that give rise to the peaks are not generally known. Overall this approach is analytically more challenging.

When metabolomics is used to target a number of metabolites of known identity, it is defined as *metabolomic profiling* or *metabolite target analysis* (depending on the number of metabolites analyzed). The targeted approach is commonly used for systems biology and biomarker discovery and readily permits the assay of several hundred metabolites in as little as 10 μ L of plasma. Although this approach is more limited, the analyses are more straightforward.

Metabolomics in Infectious Diseases

In Vitro and Animal Model Studies

Metabolomic studies performed in vitro and in animal models have provided insights into the mechanisms of infection and as biomarkers of disease severity. Using LC/MS and GC/MS, in vitro infection of cells with influenza virus identified an increase of fatty acid and cholesterol metabolites, as well as intermediates of the tricarboxylic acid (TCA) pathway.¹⁹³ In the murine model, LC/MS-based metabolomics identified lipid metabolites (5-lipoxygenase and 12/15-lipoxygenase pathways) in the lungs of infected animals that were differentially regulated based on the phase of the infection and the influenza strain virulence. These markers were subsequently confirmed in nasal wash samples from actual patients with influenza infection.²⁴³

Human Studies

In humans, targeted and nontargeted metabolomic methods allow for the identification of more than 4000 metabolites in human biofluids, and, although increasing, the number of studies are still limited.¹⁸³ Most metabolomic studies in humans have been performed in patients with sepsis to identify early biomarkers associated with improved outcomes and survival. A study conducted in a large cohort of pediatric patients with either septic shock or systemic inflammatory response syndrome (SIRS) and healthy controls identified a circulating metabolite profile that was useful for the diagnosis and prediction of mortality in septic shock.^{146,147} Other studies conducted in serum or urine samples from adult patients also with sepsis or septic shock found that metabolomic profiles had improved sensitivity and specificity over clinical scoring systems.^{71,145} A small study conducted in 30 adult patients with CAP and sepsis found broad differences in 423 small metabolites related to oxidative stress, bile acid metabolism, and stress response pathways between surviving and nonsurviving patients.²⁰⁵ In addition to sepsis, metabolomic studies have been performed in serum, oral washes, or bronchoalveolar samples from patients with TB and/or HIV for diagnostic purposes and to evaluate response to therapy.^{42,67,73,134,232} Last, a pilot study performed in urine samples from patients with HCV identified a metabolomic fingerprint that discriminated patients with HCV infection from those with HBV with high sensitivity and specificity.⁷⁶

Thus, overall, proteomics and metabolomics are promising tools, but there are still limitations to their application in the clinical setting from technical and practical points of view. From the technical perspective there are limitations in the ability to detect low-abundance, hydrophobic, or basic proteins or metabolites that often results in the lack of a complete proteome/metabolome coverage or the full proteome or metabolome dynamic range.²⁰³ From the practical point of view, analytic strategies are not completely unified, and there are two main and opposite approaches for analyses that are not yet perfected: centered (or targeted) versus unbiased.²⁶ Despite these technical limitations, the potential to develop rapid and affordable single- or small host protein- or metabolite-derived assays for the diagnosis and management of infectious diseases in the clinical setting is promising.

FUTURE PERSPECTIVES

Each infection involves the combination of a pathogen and the host response to that pathogen. In that interaction, general but also specific molecules, pathways, cells, or tissues are activated or suppressed. The use of system immunology approaches based on analyses of host responses is transforming the research landscape in the field of infectious diseases by allowing a comprehensive molecular profiling of body fluids or tissue samples in infected versus healthy individuals. These approaches (often referred to as -omics technologies) take advantage of high-throughput methods to measure all possible parameters in a given biological system. In contrast to the more traditional approach, the -omics approach is in general inherently unbiased because investigators do not need to select the parameters that will be analyzed. As an example, system vaccinology is already using this approach to identify early after vaccination differences in immune responses to vaccines.^{28,120,164} The main limitation of the -omics approach is the vast amount of data generated that need to undergo analyses and interpretation in a systematic

manner. Nevertheless, as -omics bioinformatics evolves, the ability to identify biomarkers that are predictive of specific infections and/or associated with disease severity, as well as reproducible in different patient populations, will advance in parallel. These tools will also serve to truly differentiate among infection, colonization, or asymptomatic carriage, thus allowing for an optimal use of our antimicrobial armamentarium. They may even be used to identify novel outbreaks caused by less well-identified pathogens.

Fever: Pathogenesis and Treatment

Mark A. Ward • Nicole L. Hannemann

Fever is the thermoregulated increase in body temperature above normal as the result of a coordinated response to a pathologic insult. The two essential features of fever are that it represents an abnormal elevation in body temperature and that it results from a coordinated physiologic response. The first feature differentiates fever from normal regulated elevations in body temperature (e.g., elevations associated with the circadian rhythm), whereas the latter distinguishes it from conditions in which the regulatory mechanisms are overwhelmed or dysfunctional (e.g., heat stroke). In children, the pathologic insult most likely to result in fever is infection. A variety of other conditions, including malignancies and autoimmune diseases, also may result in this phenomenon, however.

NORMAL BODY TEMPERATURE

Although the general public and physicians alike often refer to “the” body temperature, the implication that a single number can represent the thermal state of the entire body is inaccurate. Depending on the site of measurement, body temperature may vary by 1°C or more.⁴⁰ These regional variations in temperature do not have a fixed relationship to each other. Although axillary temperatures are consistently lower than rectal temperatures, the absolute difference between the two varies greatly.⁵ In addition, even in the healthy state, body temperature is not constant; it varies depending on numerous factors, such as time of day, level of activity, and phase of the menstrual cycle. Generally, clinicians

have been most interested in the core body temperature, defined as the temperature of the internal organs of the trunk and head. Under normal circumstances, core temperature is higher than the temperature of more superficial tissues such as skin. Even within these two anatomic regions, temperature gradients exist, however.

The most widely accepted definition of normal body temperature is 37°C (98.6°F).⁵¹ This number is derived from studies performed in the 19th century by Wunderlich.⁹⁹ He reportedly arrived at this figure based on the result of several million measurements conducted in approximately 25,000 individuals. Other more recent studies have found slightly lower mean temperatures in healthy individuals, despite the fact that these more recent studies are based on oral or rectal temperatures whereas Wunderlich’s studies relied on axillary temperatures.³³ Mackowiak and colleagues⁵² determined the mean oral temperature in adults to be 36.8°C (98.2°F), with the upper limit of normal ranging from 37.2°C (98.9°F) at 6:00 AM to 37.7°C (99.9°F) at 4:00 PM. Given the limitations imposed by the technology available at the time, however, perhaps the most surprising aspect of the value reported by Wunderlich is how closely it approximates these more recent determinations.

As noted previously, body temperature fluctuates depending on numerous normal physiologic factors. Core temperature shows a diurnal variation of 1°C, the nadir occurring in the early morning hours and the peak in the late afternoon.^{42,52} After exercise and in the postprandial state, body temperature increases.⁵⁸ In addition, variations in the normal

body temperature of women associated with the menstrual cycle are well described, with increases in baseline temperature occurring after ovulation.¹⁶

THERMOREGULATION

Humans, similar to other mammals, are homeothermic, indicating that they regulate body temperature within a narrow range despite wide variations in the ambient temperature. Regulation of temperature is mediated by a variety of physiologic (e.g., vasoconstriction, sweating) and behavioral (e.g., moving to a warmer environment, putting on additional clothing) responses.

The principal thermoregulatory area is located within the brain in the preoptic area and anterior hypothalamus. Although it frequently is conceptualized as a single center, no single neuronal structure seems to control all aspects of temperature regulation.¹¹ Rather, a complex interplay occurs among a variety of neural pathways, with the final result being the maintenance of the body's temperature within a narrow range. Regardless of the precise nature of central regulation, body temperature ultimately is a function of the balance between heat gain and heat loss.

Heat energy is a by-product of the inefficiency of the body's normal metabolic processes. It is this "waste" heat that renders the homeothermic state possible. During exercise, the increased metabolic activity in muscle tissue results in increased production of heat, leading to an increase in the body's temperature.⁷⁶ Shivering, an involuntary form of muscle activity, is the primary means by which the body generates additional heat under conditions of cold stress. Heat also may be generated by a process known as nonshivering thermogenesis. Originally described in rats, nonshivering thermogenesis has been found to occur in a variety of mammals, including humans. It seems to be of greater importance in neonates than in adults. Although this process has been shown to occur in a variety of tissues, brown adipose tissue seems to be the most important site for this phenomenon. Under the control of the adrenergic system, production of free fatty acid is increased, resulting in an uncoupling of oxidative phosphorylation and the production of large amounts of heat.^{10,31}

Four mechanisms are responsible for heat transfer: radiation, conduction, convection, and evaporation. Heat loss owing to radiation occurs when heat is transferred directly between two objects not in direct contact. Conduction involves the transfer of heat energy between two objects in contact with each other. Convection is the result of the movement of a fluid or gas across the surface of the body (e.g., as the result of fanning). Evaporative heat loss occurs in association with the energy required to convert liquid to gas form.

Under normal conditions, radiation accounts for most of the body's heat loss. In contrast, conductive losses are smaller under normal circumstances. Conductive losses may become substantial, however, under conditions in which a large portion of the individual's body surface is in direct contact with a cooler object (e.g., an unclothed infant in an unheated bassinet). Convective losses are proportional to the amount of air moving over the body surface; these losses are greatest in windy conditions. Conductive and convective heat losses are particularly important in infants and children because of their relatively greater body surface area compared with that of adults. Evaporative losses occur when fluids such as sweat evaporate from the skin's surface. In addition, substantial evaporative losses are associated with respiration.

PATHOGENESIS OF FEVER

In the classic model of fever pathogenesis, exogenous pyrogens stimulate the release of circulating endogenous pyrogens, which act via prostaglandins to increase the set point of the hypothalamic thermoregulatory center.¹⁸ In this model, exogenous pyrogens are substances extrinsic to the body, primarily various bacterial microorganisms or the products of those microorganisms. Conversely, endogenous pyrogens are a varied group of proteins produced within the human body that share the intrinsic ability to induce fever. The first endogenous pyrogen was described originally more than 60 years ago and was derived from

leukocytes, primarily granulocytes, and now is known as interleukin-1 (IL-1).¹⁹ Numerous other cytokines that qualify as endogenous pyrogens, including tumor necrosis factor, interferon- α , interferon- γ , and IL-6, have been identified.^{50,100}

A variety of alternative and complementary theories of fever pathogenesis have been proposed.⁵⁹ The actual mechanisms involved likely are more varied and complex than just described. A variety of intrinsically produced substances (e.g., antigen-antibody complexes) may act as "exogenous" pyrogens.⁷⁴ Murine models suggest that neuromodulatory endocannabinoid lipids play a role in lipopolysaccharide-induced fever.²⁶ The classic model provides a reasonable framework, however, for understanding most of the observed phenomena associated with the febrile response.

Regardless of the precise pathogenesis, the height of fever seems to be limited. Retrospective studies of hyperpyrexia in children have found that it is unusual for the body temperature to rise above 41.1°C (106°F), and it rarely rises above 41.7°C (107°F).^{68,91} Children with temperatures exceeding this range almost always have an element of heat illness.

EFFECTS OF FEVER

Attempts to treat fever often are predicated on the assumption that fever has harmful effects and that reduction in temperature would abrogate such harm. The evidence with regard to these premises is mixed, however.

Adverse Effects

Some animal studies have found that high fever may impair certain immunologic responses, including phagocytosis of staphylococci by polymorphonuclear leukocytes^{6,23,25} and lymphocyte transformation in response to mitogens.⁷³ Whether these isolated in vitro phenomena observed in animal models are relevant to human infection is unknown.

Fever may cause seizures, a phenomenon observed most frequently in young children. The onset generally occurs in infants 6 to 30 months of age. Recurrence is common, occurring in approximately one third of children experiencing an initial febrile seizure. The primary adverse consequences of febrile seizures are the emotional distress experienced by patients and their families and the need for medical evaluation, which may involve invasive testing and substantial expense. Febrile seizures do not cause brain injury and are not associated with subsequent intellectual or neurologic deficits.^{22,93} Furthermore, numerous studies have failed to demonstrate that use of antipyretics is effective in preventing febrile seizures.^{61,78,88}

An important nonphysiologic adverse effect of fever is caregiver anxiety, reflecting an underlying concern for harm due to untreated fevers despite a lack of supporting data.⁶⁵ The unfounded anxiety is not limited to the lay public.⁶⁶ In addition, fear phobia may be inadvertently reinforced by the actions of medical personnel; for example, it has been observed fever may routinely be treated more promptly than pain in the pediatric emergency room.²¹ Caregiver distress also crosses cultural boundaries, as suggested by a recent Turkish study that revealed that 3 out of 4 parents would wake their child from sleep to administer antipyretics.⁶⁷

Beneficial Effects

Fever may be beneficial by enhancing the host response to infection and by directly inhibiting the infecting agent. Several studies have demonstrated that the immune system responds to mildly elevated body temperature by increasing migration of leukocytes, production of interferon, and lymphocyte transformation and phagocytosis.^{2,8,73,75} Studies of bacterial infection in reptiles and fish have shown an increased survival rate in groups maintained at approximately 4°C (reptiles) and 2.5°C (fish) above baseline.^{15,43} Kluger and Vaughn⁴⁵ showed that rabbits infected with *Pasteurella multocida* had improved survival rates at body temperatures of approximately 4.5°C above normal. Although these data are impressive, their clinical significance with regard to humans has yet to be determined.

Fever also may inhibit the growth and survival of some infectious agents. One potential mechanism for this inhibition is the decrease in serum iron and increase in ferritin that are associated with fever, coupled

with the increased iron requirement of many bacteria at higher temperatures.^{6,44} Fever therapy was used historically to treat neurosyphilis and gonococcal urethritis, correlating with more recent studies that show that certain gonococci and *Treponema* are eradicated at temperatures of 40°C (104°F) and greater.^{13,41} Finally, growth of some pneumococci and viruses seems to be impaired at higher temperatures.^{30,86,94}

Several studies have found that the treatment of fever with antipyretics is associated with adverse consequences, providing indirect evidence of a beneficial effect of fever. Ahmady and Samadi² reported that the use of aspirin in children with measles prolonged the duration of the illness and was associated with an increase in prevalence of respiratory complications and diarrhea. Other investigators have reported that the length of time to total scabbing in varicella was significantly longer in children treated with acetaminophen compared with children treated with placebo.²⁰ Several studies in animal models and in humans have found prolongation of viral shedding, depressed neutralizing antibody response, and increased nasal symptoms in association with the use of antipyretics.^{28,36,90} Although these studies establish that an association exists between reduction of fever and adverse outcomes, they do not prove a causal relationship. The adverse effects possibly are mediated by some direct physiologic effects of antipyretics rather than indirectly by their impact on fever.

CLINICAL THERMOMETRY

Types of Thermometers

For many years, glass thermometers containing mercury were the most common type of thermometer used to measure body temperature. This type of thermometer is reasonably accurate for most clinical purposes. Although they are still available, use of mercury-containing thermometers has diminished greatly because of environmental concerns about mercury exposure from broken or discarded thermometers. These thermometers have been replaced largely by digital thermometers or glass thermometers containing liquids other than mercury.

Electronic thermometers (often referred to as digital thermometers) previously were used primarily in the hospital and office setting. As their cost has decreased, they are used more frequently in the home as well. Electronic thermometers have the advantage over mercury thermometers of requiring a significantly shorter dwell time—that is, the time they must remain in situ to obtain an accurate reading. Hospital-grade electronic thermometers typically have two modes: monitor and predictive. In the monitor mode, these thermometers function similarly to mercury thermometers in that they must remain in place until equilibration occurs, a process that may require several minutes. In the predictive mode, a complex algorithm is used to estimate the final temperature based on measurements made during the first few seconds. Because the predictive mode produces a temperature reading within seconds, it is the mode used most often in clinical settings. Determinations of temperatures using these two modes have been found to correlate well.^{25,60}

Infrared thermometers are a more recent addition to the clinician's armamentarium. Devices that determine the temperature by detecting infrared radiation emitted from the eardrum are used most frequently. Tympanic temperature should provide an accurate estimation of the core temperature because its blood supply is derived from the carotid artery. Additional advantages of this type of thermometer are its speed, acceptance by patients, and decreased risk of cross-contamination compared with oral or rectal thermometers. Studies of the accuracy of tympanic thermometers have yielded mixed results, with numerous studies finding tympanic thermometers inaccurate compared with mercury in glass or electronic thermometers.^{14,56} A recent meta-analysis showed pooled sensitivity of 70% and specificity of 86% as compared to rectal thermometry in diagnosing pediatric fever.¹⁰¹ Discrepancies seem to be particularly common in infants who are in the first few months of life.⁸³ Tympanic thermometers should not be used in young infants because of the importance of fever in making management decisions in these patients.¹⁷

Even more recently, the temporal artery thermometer has been introduced. These thermometers use an infrared sensor to determine skin temperature as the device is passed across the forehead and temporal

area. The site of highest measured temperature is assumed to represent that of the temporal artery. An algorithm is applied to the measured temperature to estimate the core temperature. Studies to date suggest that temporal artery thermometer temperatures correlate significantly better with rectal and core temperatures than with temperatures determined by tympanic thermometers. The data also suggest that these thermometers are more sensitive at detecting fever in children than in adults. Temporal artery thermometers do not seem to correlate well enough with rectal or core temperature measurements, however, to replace rectal thermometry in clinical situations in which accurate measurement of fever is crucial for making decisions about management. Correlation with rectal thermometry may be particularly limited in children younger than 36 months of age, with a reported sensitivity as low as 27% to 53%.³² The accuracy of temporal artery thermometer readings is adversely affected by sweating and may be affected by vascular constriction or dilation. In addition, data comparing temporal artery and axillary thermometry are lacking.^{29,89}

Several other types of thermometers have been developed. Among them are electronic pacifier thermometers, which are used for obtaining an oral temperature in infants. Although they are appealing in theory, this type of thermometer has the disadvantage of requiring a prolonged dwell time and has not been found to be sufficiently accurate to recommend its use.⁶⁹ Another approach to measuring temperature is the use of liquid crystal thermometers that are applied to the skin of the forehead. Results generally have been disappointing when these thermometers have been compared with more standard techniques.^{46,79}

Despite ready availability of thermometers, many parents continue to utilize palpation, generally of a child's forehead, to detect the presence of fever. A study of infants under the age of 3 months found the positive predictive value of this practice to be only 33%, although the negative predictive value was as high as 95%. These results support the conclusion that palpation should not be used as the sole means of fever assessment.³⁸

Measurement Site

The most common locations for measuring body temperature are the mouth, rectum, axilla, and tympanic membrane. Because of the previously noted regional variations in body temperature, each of these sites has its own range of normal temperatures. The oral cavity historically has been the preferred site for measuring temperature in older children and adults. When taking a temperature orally, one should place the thermometer in the sublingual space because the blood supply for structures in this region is derived from branches of the carotid arteries and should reflect the core temperature accurately. Younger children usually are unable to cooperate adequately to permit the use of oral thermometers. In addition, the oral temperature may be affected by recent ingestion of hot or cold liquids, and it may be altered by tachypnea.

Rectal temperatures are used frequently in younger children. The rectal temperature correlates well with the core body temperature. The rectal temperature may exceed the core temperature (using the pulmonary artery temperature as the reference standard), however, possibly because of the effects of bacterial activity in the rectum. The use of rectal thermometry has the disadvantage of causing the patient discomfort and is contraindicated in patients with neutropenia because of the risks of causing invasive infection via trauma to the rectal mucosa.

Axillary temperatures are appealing because of the ready accessibility of the axillae. Considerable variability occurs in the readings obtained, however, particularly in younger children. One should not rely on axillary temperatures, particularly in neonates and young children.

TREATMENT

As noted previously, fever may have numerous beneficial effects, convincing evidence of harm owing to fever is lacking, and treatment of fever may be associated with undesirable effects. Therefore routine intervention to reduce fever is not warranted. Rather physicians should individualize the decision to treat fever and the specific method chosen to do so. This approach is in accordance with the recommendations of the American Academy of Pediatrics.⁸²

Indications

Antipyretic therapy often is considered for children who have an increased risk of having febrile seizures, either because of age or because of a history of febrile seizures. Although treatment seems rational in this situation, studies of antipyretic therapy to prevent febrile seizures have repeatedly failed to demonstrate its efficacy.^{12,61,78,88,92} Even this indication should be considered relative rather than absolute.

Prophylactic administration of acetaminophen prior to routine immunizations to prevent vaccine-related fever has been debated. The practice is generally not recommended due to lack of supporting evidence. While the American Academy of Pediatrics Red Book recommends considering acetaminophen administration before and after DTaP immunization for children with a personal or family history of seizures,⁴ studies have generally failed to produce results to support this practice.⁵⁴

Antipyretic therapy also should be considered for children with poorly compensated underlying cardiac or pulmonary disease, significant neurologic impairment, or sepsis and for children with significant alterations of fluid and electrolyte balance. Definitive controlled trials to support these indications are lacking. Rather the recommendations are based on the metabolic consequences of fever and their potential adverse impact on the underlying disease.

Perhaps the most frequent indication for the use of antipyretics is to improve the patient's comfort. Despite the absence of definitive studies to support this practice and the potential adverse consequences of using antipyresis, such an approach is reasonable in the absence of definitive evidence to the contrary. In some circumstances, improving the patient's comfort may enhance the ability to assess the seriousness of the patient's illness accurately.⁷

Antipyretics

A wide variety of antipyretic agents is available. In the United States, the drugs used most frequently for treatment of fever in children are acetaminophen and ibuprofen. Previously, aspirin was the antipyretic used most frequently. Aspirin has fallen into disuse for the management of fever in children, however, primarily because of its association with Reye syndrome, particularly when used in managing children with varicella or influenza.³⁵ In addition, aspirin has a variety of other adverse effects, including inhibition of platelet function, gastritis and gastrointestinal bleeding, and provocation of asthma exacerbations, although this third complication occurs more frequently in adults.^{37,72,81} Aspirin has greater toxicity in situations of overdose than do acetaminophen and ibuprofen.

Each of these agents acts to restore normal body temperature by reducing the set point of the temperature regulatory center in the hypothalamus. The specific mechanism of action seems to be interference with prostaglandin synthesis in the preoptic anterior hypothalamus. When selecting among the available antipyretic agents, one should consider efficacy and potential toxicity.

Similar to aspirin, ibuprofen inhibits prostaglandin synthesis in a variety of tissues outside the central nervous system. It shares many of the toxicities associated with aspirin. One exception is that ibuprofen lacks the association with Reye syndrome.⁷⁰ Ibuprofen inhibits platelet function because of its effect on prostaglandin synthesis, but this effect is reversible with discontinuation of the drug, and platelet dysfunction is short lived compared with the effect of aspirin.⁶² Because prostaglandins are important to the integrity of the gastrointestinal mucosa, inhibition by ibuprofen may result in gastrointestinal upset and bleeding. Although ibuprofen has been associated with exacerbations of asthma in some children, the risk seems to be small and may not be greater than that associated with the use of acetaminophen.^{47,48}

Acetaminophen has a lengthy track record of safety. When used in the usual therapeutic doses, it has few adverse effects. Acetaminophen inhibits prostaglandin synthase activity, but this action is inhibited by peroxide. Because peroxide is generated at sites of inflammation, acetaminophen has little anti-inflammatory activity. It also lacks the adverse gastrointestinal and platelet effects of aspirin and ibuprofen. A growing body of evidence suggests that acetaminophen use is associated with an increased risk of subsequent asthma.²⁴ Despite the fact that studies have consistently found this association, evidence of a causal relationship has yet to be conclusively established. Recommended dosing

of ibuprofen is 5 to 10 mg/kg every 6 hours as needed. Acetaminophen is administered at a dose of 10 to 15 mg/kg every 4 hours but no more frequently than five times per day. An important note for individuals administering these agents is that a variety of over-the-counter combination medications contain one or the other of these agents. Co-administration may result in inadvertent overdosing.

In addition, recognition that ibuprofen and acetaminophen come in a variety of formulations is important.⁸⁵ Acetaminophen, once available as infant drops (concentration 10 mg/mL) and children's liquid (concentration 32 mg/mL) is now only available in a single concentration (32 mg/mL). The voluntary removal from the market of the more concentrated formulation was prompted by reports of inadvertent overdose from substitution of infant drops for the children's liquid without adjusting the volume administered to reflect the difference in concentration. Acetaminophen also is available in suppository form. Absorption varies, however, and is delayed compared with oral administration. In addition, the medication is not distributed uniformly throughout the suppository, resulting in potential dosing errors if the suppositories are divided before use.⁹ The use of acetaminophen in suppository form should be discouraged. Ibuprofen continues to be available in two concentrations: a children's liquid (20 mg/mL) and infant drops (40 mg/mL). The dual concentrations create the potential for incorrect dosing seen previously with acetaminophen.

The antipyretic efficacy of acetaminophen and ibuprofen has been the subject of numerous clinical trials.^{39,95-97} These trials have shown uniformly that both are effective antipyretic agents. Ibuprofen seems to result in a greater decrease in temperature than does acetaminophen, however. In addition, the antipyretic effect of ibuprofen is more prolonged, not surprising in light of ibuprofen's longer half-life compared with acetaminophen. These observations were confirmed in a meta-analysis of trials comparing ibuprofen and acetaminophen.⁶⁴

Acetaminophen and ibuprofen frequently are used in combination.⁴⁹ Use of alternating doses often is advocated by practicing physicians.^{55,98} The pathways for metabolism of these drugs are distinct, and, theoretically, metabolism of one should not affect the metabolism of the other. Controlled trials documenting safety and efficacy of combination or alternating use are sparse, however. In one study, using alternate doses of acetaminophen (12.5 mg/kg per dose) and ibuprofen (5 mg/kg per dose) every 4 hours was found to be associated with a more rapid reduction in fever, lower mean temperature, and fewer caregiver days absent from work and infant days absent from daycare compared with use of either agent alone.⁷⁷ However, the groups assigned to a single agent received dosing that was either on the low end or infrequent compared with usual practice in the United States. In a more recent study utilizing full therapeutic doses and comparing ibuprofen alone with alternating and combined schedules of ibuprofen and acetaminophen, the alternating and combined schedules were found to provide greater antipyresis.⁶³ Recent systematic reviews of combination versus single-agent treatment with acetaminophen and ibuprofen concluded that the antipyretic effect of combined therapy was statistically superior but the clinical relevance was marginal at best. Furthermore the studies found no evidence of increased toxicity with combined treatment but were not designed to definitively address the issue.⁷¹ Evidence is also lacking regarding any beneficial effects of combined therapy on child discomfort.⁹⁸

Another approach to antipyretic treatment frequently employed is the use of a second antipyretic when the initial agent is judged to have resulted in an inadequate response. Theoretically, some individuals may have a better antipyretic response to one agent than another. Although the premise is reasonable, sequential use of acetaminophen and ibuprofen remains unproved in terms of efficacy and safety.

Acetaminophen and ibuprofen have been proved to be remarkably safe when used in the recommended doses. Although ibuprofen may be slightly more efficacious in producing and sustaining fever reduction, acetaminophen remains the antipyretic of choice because of its longer track record and more favorable side-effect profile. Because acetaminophen lacks significant antiinflammatory activity, ibuprofen or another nonsteroidal antiinflammatory drug may be preferred in febrile conditions for which antiinflammatory activity is desired (e.g., juvenile arthritis). Limited data suggest that use of acetaminophen and ibuprofen

in combination may be safe and more efficacious than is either agent alone. Prudence suggests, however, that combined therapy seldom is warranted for the treatment of fever, a generally benign condition. Perhaps most important, patients and their parents should be educated about the benign nature of fever and the lack of evidence to indicate that routine treatment, particularly complete suppression, is either necessary or beneficial.

External Cooling

The use of external cooling in the management of fever has a long history. Compared with standard antipyretics, sponging with tepid water is inferior in fever reduction at 2 to 3 hours, although sponging was found to reduce the temperature more quickly than did antipyretics in one trial.^{1,3} External cooling without concomitant administration of antipyretics makes little sense from a physiologic standpoint, however. In a febrile patient whose temperature regulatory center set point has not been reset by administration of an antipyretic agent, external cooling inevitably results in an increase in the body's heat-production mechanisms.

When used in conjunction with an antipyretic agent, the usual goal of external cooling is to reduce the body's temperature more rapidly or to a greater degree. Several studies have compared the use of external cooling combined with antipyretics with antipyretics alone. Results have been mixed; some studies showed no difference in efficacy of the two approaches, whereas others found combination therapy to be superior.^{27,34,53,84,87} Even in the studies in which a difference was found, the superiority of combination therapy was shown primarily in the very early phase of treatment. A recent randomized controlled study performed in an adult critical care unit population concluded that external cooling decreased vasopressor requirements and early mortality in septic shock. However, it is unclear if these results can be translated to the pediatric population.⁸⁰

In addition, the use of external cooling usually is uncomfortable for the patient. When external cooling is to be used, sponging with tepid water is preferred. Alcohol and solutions containing alcohol should not be used for this purpose. Absorption of alcohol vapors via the lungs may occur in sufficient quantities to produce toxicity and even death.⁵⁷

SUMMARY

Fever represents an abnormal increase in body temperature resulting from a coordinated physiologic response to pyrogens. While a variety

of newer modalities are available, rectal thermometry remains the preferred method for temperature measurement when accuracy is important. Routine antipyretic therapy is not recommended in the absence of patient discomfort or concern for the effects of increased metabolic demand because there are few proven adverse effects of fever. When antipyresis is desired, acetaminophen and ibuprofen are generally safe and effective agents for that purpose.

The Human Microbiome

Berkley Luk • Douglas S. Swanson • James Versalovic

INTRODUCTION

The human microbiome consists of different microbial communities colonizing specific body sites (Fig. 5.1) and fluctuating during several life stages. Because pediatrics is fundamentally oriented around the health and pathophysiology of the developing human, the rapid accumulation of new findings in microbiome science during the past decade provides a new frame of reference for human growth and development. Human microbes are part of the conversation regarding human physiology during fetal development even before birth, and these microbial communities continue to shift and develop during infancy and childhood. Beyond microbial composition, functional

features of microbial metabolism are leading to the identification and rediscovery of potentially important bioactive compounds originating from the microbiome. Dietary changes, so prominent in early childhood, clearly impact the biology of the microbiome early in life and may have important consequences for disease risk.

Antibiotics may suppress and eliminate many commensal microbes, placing the host at risk for disorders of microbial ecology such as *Clostridium difficile* infection. Diet and antibiotics represent two major environmental factors affecting the biology of the microbiome, with potentially deleterious effects on microbial diversity and resilience of microbial communities. Commensal microbes produce a variety of antimicrobial compounds that modify microbial composition and may

FIG. 5.1 The composition of bacterial, fungal, and viral microbiota at distinct body sites. This figure shows the distribution and relative abundance of bacterial, fungal, and viral communities at different sites on the human body that are exposed to the external environment. Bacterial composition is represented by the six most abundant phyla, fungal composition by the most prominent genera, and viral composition as bacteriophages or eukaryotic viruses. (Modified from Marsland BJ, Gollwitzer ES. Host-microorganism interactions in lung diseases. *Nat Rev Immunol.* 2014;14:827–35.)

help the host defend against pathogens. Beneficial microbial species may induce the production of antimicrobial peptides, such as defensins, by the host. During infection, bacterial and other pathogens may have a profound impact on the composition and biology of the microbiome. Humans inhabiting this microbial world must coexist and thrive with indigenous microbial communities during growth and development. This intimate partnership between microbes and infant/child may affect susceptibility to pediatric infections and modulate the course and severity of infectious diseases.

DEVELOPMENT IN EARLY LIFE THROUGH CHILDHOOD

The fetus and neonate are exposed to microbial communities during prenatal and early postnatal development.¹ Descriptions of a placental microbiome highlight the presence of functionally dynamic microbial communities at the maternal-fetal interface. Even if microorganisms do not directly contact the fetus, microbial metabolites may have an impact on fetal development. The presence of microbes in the colostrum and amniotic fluid provides evidence that placental microbes may contact the fetus via the circulation.^{22,50,51} Mouse models indicate that bacterial species such as *Fusobacterium* spp. may “home” specifically

to the placenta via the bloodstream.^{42,82} This finding emphasizes a key point that the placental microbiome is most similar to the oral microbiome, lending support to the concept that the oral microbiome may provide founder bacterial species for the placental microbiome in the early stages of pregnancy.¹ The presence of oral pathogens may place the fetus at risk if oral pathogens can traverse the bloodstream and seed the placental microbiome. As we consider the nature of infections in utero in maternal-fetal medicine, this connection between the oral and placental microbiomes may point to new strategies to evaluate the oral microbiome before or during pregnancy and provide additional information regarding potential risks for the fetus. Additional concepts based on experimental data include differences in the placental microbiome in cases of preterm birth and whether differences in microbial composition or function may place the fetus at increased risk of preterm birth.^{1,63} Microbial metabolites such as microbe-derived calcium channel blockers may affect contractility of the uterine musculature and the tendency toward premature contractions prior to childbirth.⁶⁸ Prior antimicrobial therapy has a fundamental impact on the composition of the placental microbiome, and antecedent antimicrobial exposure yields significant differences in the placental microbiome that could affect fetal development and preterm birth. All of these conceptual points highlight the rapidly emerging understanding

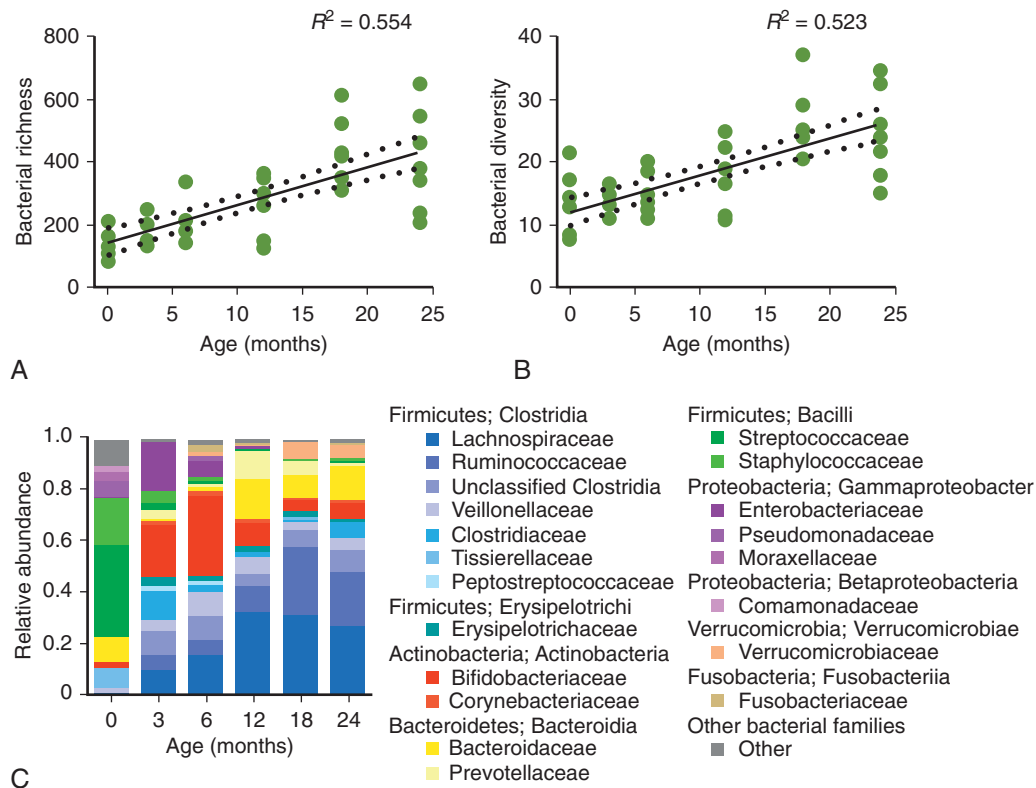

FIG. 5.2 Changes in the bacterial community structure in infants over time. (A) Richness (number of observed bacterial OTUs) of bacterial OTUs ($n = 8$ infants). Linear regression, R^2 value, and 95% confidence intervals are shown. (B) Bacterial α diversity (Faith's phylogenetic diversity) ($n = 8$ infants). Linear regression, R^2 value, and 95% confidence intervals are shown. (C) Relative abundance of bacterial families based on 16S rRNA gene sequences. Statistical significance was assessed by Student's t test; $P < .01$. OTU, Operational taxonomic unit. (Modified from Lim ES, Zhou Y, Zhao G, et al. Early life dynamics of the human gut virome and bacterial microbiome in infants. *Nat Med*. 2015;21:1228–34.)

of the impact of the microbiome on the health and disease susceptibility of the fetus.

Several studies have indicated that the neonatal and infant gut microbiome develops rapidly after birth and may influence susceptibility to enteric infections and acute disease. The neonatal microbiome matures rapidly in terms of microbial acquisition, and relatively complex microbial communities form in the intestine and other body sites by the end of postnatal week 1.^{24,67} Microbiome development continues at a rapid pace and with relatively large-scale fluctuations in composition and function during infancy^{54,59,94} (Fig. 5.2). Immediately after birth, the neonate is colonized by various microbes belonging to different phyla at different body sites.⁹⁵ The major phyla that are established in the human body by the end of infancy include Bacteroidetes, Firmicutes, Proteobacteria, and Actinobacteria. One of the hallmarks of the early neonatal microbiome is that microbial composition does not differ significantly by body site.²⁴ It takes weeks or months during infancy to see evidence of “differentiation” of distinct microbial communities at each body site. Within days, different body sites are rapidly colonized, but these communities gradually change to reach a steady state of microbial communities that are highly adapted for a specific body site. This process of “microbiome differentiation” may have important consequences for infectious disease risk depending on the nature and timing of the infection.

At approximately 4 to 6 weeks age, the microbiomes at different body sites are clearly distinguishable, and the impact of mode of delivery on microbial composition is negligible.⁹⁵ By 2 to 3 years of age, it appears that the intestinal microbiome is comparable to the adult microbiome in terms of complexity.^{54,94} The impact of diet on microbial composition during the first 3 years of life is dramatic, and breast milk to solid food transitions clearly change the composition and function of the intestinal microbiome.^{27,54} During childhood and prior to adolescence, the pediatric

intestinal microbiome continues to differentiate in terms of microbial composition and function.⁴⁶ The relative richness of the microbiome in childhood actually exceeds that of healthy young adults, so presumably bacterial species are culled during adolescence. Although the major phyla are established during infancy, the relative preponderance of different phyla differs between school-aged children and young adults. For example, children have a greater relative abundance of Firmicutes relative to Bacteroidetes, and genera such as *Bifidobacterium* and *Faecalibacterium* are enriched in children.⁴⁶ Children also contain specific functional elements, such as pathways for vitamin B₁₂ and folate biosynthesis, which are enriched in the pediatric gut microbiome. These pathways may promote hematologic and central nervous system development. Firmicutes including clostridia may produce short-chain fatty acids (SCFAs) that can suppress enteric pathogenesis, and specific commensal species may produce various antimicrobial peptides and propionaldehyde compounds that suppress enteric pathogens.

IMPACT OF ENVIRONMENTAL FACTORS: DIET AND MEDICATIONS

Various environmental factors such as dietary food intake and consumption of medications may influence and modulate the composition and function of the human microbiome in different body sites. Breast milk drives predictable changes in microbial composition, and infants receiving breast milk clearly differ by intestinal microbial composition when compared to formula-fed infants.^{5,11,77} Human breast milk contains indigenous microbes including *Bifidobacterium*, *Lactobacillus*, and *Streptococcus* species, and these species colonize the gut microbiome of infants shortly after initiation of breastfeeding.⁴¹ The gastrointestinal microbiome rapidly expands in terms of richness and diversity during the first weeks of life if the infant is consuming breast milk and avoiding

antimicrobial agents. Breastfeeding results in changes to the microbiome and host that result in reduced susceptibility to necrotizing enterocolitis (NEC).^{39,78} The addition of solid foods to the diet results in the next wave of profound changes to the gastrointestinal microbiome during the first 3 years of life, and these changes may affect relative susceptibility to enteric infections during childhood.^{23,54,89} Comparisons of children from western Africa (Burkina Faso) consuming a diet rich in cereals, vegetables, and plant fiber with children from Western Europe (Italy) on a diet enriched in animal protein, sugar, and fat yielded dramatic differences in gut bacterial composition at the phylum level. Children from Italy yielded gut microbiota dominated by the Firmicutes and Proteobacteria phyla, whereas children from Burkina Faso yielded microbiota more abundant in Actinobacteria and Bacteroidetes.²⁰ A diet rich in plant polysaccharides and low in sugars and fats is predicted to increase microbial diversity and therefore confer protection from enteric pathogens. Although host genetics, sex, and geography are known to influence the composition of the gut microbiota, accumulating evidence suggests that diet has a relatively large impact on biodiversity within the gut ecosystem.^{13,80,93}

Dietary manipulation by the addition of beneficial microbes (probiotics) or creation of highly specialized diets may prevent infectious diseases or facilitate management of chronic intestinal disease phenotypes. Consumption of probiotics may dramatically alter the microbial composition and function of the pediatric intestinal microbiome, principally by changes in microbial gene expression and microbial metabolism.^{8,18} Ingestion of probiotics during infancy reduced the risk of enteric infections, and probiotics may protect children from acute gastroenteritis.^{48,91} On the other side of the spectrum, a restricted elemental diet used for treating pediatric patients with Crohn's disease further reduced the biodiversity of the gastrointestinal microbiome while ameliorating symptoms.^{53,70} In addition to dietary manipulation, medications may have a profound impact on microbial composition and function in the intestine. Antimicrobial agents administered in the first few days of life to neonates may delay colonization of the intestine and could increase the risk of enteric infections by reducing colonization resistance in the host.^{29,67,69} (Fig. 5.3). Different classes of antimicrobial agents may have different effects on the intestinal microbiome, and we are just beginning to appreciate the different risks associated with exposure to different antimicrobial agents.^{34,92} A classic example is recurrent *C. difficile* infection and antimicrobial-associated diarrhea due to treatment with antimicrobial agents such as cephalosporins and fluoroquinolones.

BODY METABOLISM AND IMMUNITY

SCFAs are well-known examples of microbial metabolites affecting the intestinal epithelium. Three main SCFAs produced in the human colon are acetate, propionate, and butyrate. Propionate and acetate affect adipogenesis and leptin production. By modulating gut- and adipocyte-derived hormones, SCFAs may affect the gut-brain axis and brain function, including appetite and satiety.^{26,64} Acetate is able to directly affect neuronal function in the brain, especially regions associated with appetite.³⁰ With respect to enteric infections, Shiga toxin-producing strains of *Escherichia coli* can produce serious, life-threatening infections in children, resulting in hemolytic uremic syndrome and renal injury. Studies in mouse models indicate that *Bifidobacterium* species can suppress translocation of Shiga toxin across the intestinal epithelium and that the organic acid acetate contributes to this effect.³¹ B-complex vitamins including vitamin B₁₂ are also produced by bacterial members of the intestinal microbiome, and vitamin B₁₂ may suppress Shiga toxin by *E. coli*.^{19,74} Bioactive compounds produced by the commensal intestinal microbiota may regulate toxin production by enteric pathogens and reduce susceptibility to enteric infections.

Beneficial microbes may convert tryptophan into bioactive indole compounds. Indole derivatives act as endogenous ligands for the arylhydrocarbon receptor (AhR)⁴⁴ and are generated from dietary tryptophan by commensal intestinal microbes.¹⁰ By binding AhR, the microbiota may stimulate mammalian immune cells to produce the cytokine interleukin (IL)-22, thereby enhancing protective mucus production, suppressing IL-17 production, and stimulating production

of antimicrobial peptides via signal transducer and activator of transcription 3 (STAT3) activation. The lesson in *Lactobacillus*-mediated indole-3-aldehyde (one example of an indole derivative) production from tryptophan is that bacterial metabolites generated by the microbiome may have a profound impact on immunity. The *metabiotic concept* refers to metabolites produced by the microbiome or probiotic species that may confer specific benefits on mammalian physiology or immunity. The mammalian tryptophan catabolic enzyme indoleamine 2,3-dioxygenase 1 (IDO1) plays a key role in the conversion of dietary or microbial tryptophan into kynurenines and promotes tolerance to commensal microbes. The capacity of IDO1-expressing dendritic cells, epithelial cells, and kynurenines to induce regulatory T cells (Tregs) and inhibit T-helper 17 cells (T_H17) has revealed their unexpected potential to control inflammation, allergy, and T_H17-driven inflammation in fungal infections.^{40,71}

Amino acid decarboxylation systems, such as the glutamate decarboxylase (GAD) or histidine decarboxylase (HDC) systems, enable bacterial species to cope with acid stress in the gastrointestinal tract. These systems are providing insights into infectious diseases and intestinal inflammation as it pertains to childhood. The bacterial GAD system is enriched in the intestinal microbiome relative to other body sites of healthy adults, and γ -aminobutyric acid (GABA) is enriched in the intestines of patients with recurrent *C. difficile*-associated disease (CDAD).⁹⁶ Most intestinal GABA measured in stool is microbial in origin, and this metabolite appears to potentiate the risk of *C. difficile* infection. Individuals consuming the GABA_A receptor agonist zolpidem (Ambien) have increased risk of *C. difficile* infection, adding support to the potentially pathogenic role of GABA in recurrent CDAD in children.⁹⁷ Microbial species in the human gut can also convert L-histidine to histamine. This biogenic amine may promote allergic inflammation, suppress intestinal inflammation, or function as a neurotransmitter in the central nervous system by binding to any of the four different histamine receptors found on human cells. Antihistamines function by blocking signaling through the histamine 1 or histamine 4 receptors (H₁R and H₄R), and these receptors are considered proinflammatory.⁸⁷ In contrast, histamine may promote gastric acid production and suppress intestinal inflammation via H₂R. Although H₂R blockers have been useful as adjunct medications in the treatment of *Helicobacter pylori* infection,³⁵ they may also promote mucosal or systemic inflammation. Studies in the pediatric literature have documented increased risk of and mortality from NEC in newborns exposed to H₂R blockers.^{84,85} Gut microbes may generate histamine in the small or large intestine and serve as a checkpoint for immunoregulation in the gastrointestinal tract. These amino acid metabolites may have opposing effects in terms of mucosal immunity, and microbe-derived compounds may help modulate susceptibility to pediatric infections.

MICROBIOME AT DIFFERENT BODY SITES

Airway and Respiratory Tract Microbiome

The fetal airway is likely exposed to microbial influences in utero due to the direct contact between the respiratory tract and the surrounding environment.¹ However, bacterial niches in the airway are vastly different after birth as the respiratory tract transitions from a fluid-filled cavity to a functional organ involved in gas exchange. Upon exposure to the external environment, the human respiratory tract is rapidly colonized by a community of commensal bacteria that gradually matures and diversifies during the first year of life. Skin-associated bacterial genera including *Staphylococcus* and *Corynebacterium* species are detectable in the upper respiratory tract on the first day of life and are dominant up to 3 months of age.⁸³ The prevalence of these species steadily declines from birth to 6 months, and these microorganisms are succeeded by other bacterial species such as *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae*.^{3,9,83} Geography, season of birth, environment, social interactions, and presence of older siblings are primary determinants of colonization rate and sources of bacterial acquisition.^{7,12,43} The infant lung has distinct compartments with different growth conditions allowing enhanced growth of Bacteroidetes, unlike the upper respiratory tract, which is dominated by Firmicutes and Proteobacteria.^{61,83} Microbiota traverse the upper and lower respiratory

FIG. 5.3 Early host-microbiota interactions in health, antibiotic-induced dysbiosis, and disease. Interactions between early microbial colonizers of the intestinal tract and the host immune system contribute to proper immune maturation during normal development. Antibiotic-induced dysbiosis during this critical window can lead to improper immune system development resulting in allergy and atopic and autoimmune diseases. Early antibiotic use can also reduce diversity in the gut and promote blooms of potential pathogens resulting in a local inflammatory response. This inflammatory gut environment may persist and result in increased predisposition to chronic infections. (Modified from Vangay P, Ward T, Gerber JS, Knights D. Antibiotics, pediatric dysbiosis, and disease. *Cell Host Microbe*. 2015;17:553–64.)

tracts via mucosal extension, microaspiration, and ciliary transport. These factors along with local growth conditions in human airways, immunity of the respiratory tract, and microbial crosstalk contribute to the community structure at specific locations within airways. Interactions between the intestinal and respiratory microbiota have been suggested, and early nutritional exposures may also influence the developmental trajectory of the respiratory microbiome.⁶⁰

Dynamic changes in the composition of the respiratory tract microbiome during the first year of life may affect the development of the respiratory mucosal immune system. The pattern of immune responses in the respiratory tract modulates relative susceptibilities to allergic inflammation or respiratory tract infections.⁸⁸ A diverse, homeostatic microbiome is necessary for immune priming and defense

against pathogen overgrowth and invasion.³² Microbial exposure in the lung during the first 2 weeks of life induces a programmed cell death ligand 1 (PDL1)-mediated tolerance to aeroallergens.³⁶ Relatively limited biodiversity and bacterial load in the airways are associated with improper development of regulatory immune cells, leaving the host susceptible to allergic inflammation lasting into adulthood.³⁶ The composition of the microbial community in the upper respiratory tract also influences the susceptibility of the lower airways to viral infections and affects the severity of the resulting inflammatory response.⁸³ Antibiotic use and inflammation resulting from viral infections can also lead to dysbiosis and the development of early allergic sensitization.⁶¹

Early colonization with a diverse respiratory microbiota is associated with a decreased risk of developing asthma, and overall microbial

community composition appears to be a main determinant for asthma. Relative overgrowth of specific bacterial species may exacerbate the risk of developing asthma in genetically predisposed newborns.^{4,61,83} Beyond allergic inflammation, physicochemical alterations in chronic lung disease may alter the airway microbiota and susceptibility to respiratory tract infections. Disruption of the microbial ecosystem can be a consequence of host factors such as cystic fibrosis in which increased mucus production and impaired mucociliary clearance result in altered local growth conditions and reduced microbial clearance favoring the growth of specific respiratory pathogens.

Gastrointestinal Microbiome

The intestinal microbiome develops rapidly after birth in both premature and full-term infants. In premature infants the succession of bacterial classes demonstrates a temporal sequence shifting from a relative abundance of Bacilli (gram-positive aerobes) to Gammaproteobacteria (gram-negative facultative anaerobes).⁵⁷ Both Clostridia and Gammaproteobacteria increase in relative abundance with increasing postconceptional age. Since the class Gammaproteobacteria contains several potential enteric pathogens, perhaps these microbes promote complete maturation of the intestinal immune system. Alternatively the gut milieu accommodates a greater variety of microbes with time during infancy, including potential pathogens. Potential pathogens lurking in the intestinal microbiome early in life may invade the bloodstream of premature infants.¹⁶ Pathogenic bacteria such as *E. coli*, group B streptococcus (GBS), and *Serratia marcescens* were documented in the intestinal microbiomes of premature infants prior to late-onset sepsis by the same microbes (verified by molecular epidemiology/sequencing).¹⁶ Additionally, ciprofloxacin-resistant *E. coli* were isolated from children and their mothers, and maternal colonization by drug-resistant bacteria was correlated with childhood carriage of the same organisms. Therefore, the presence of potential pathogens and drug-resistant microbes in the intestine may have important implications for familial transmission and infection risk.

A classic example of infectious disease risk associated with assaults on the intact microbiome is the category of antimicrobial-associated diarrhea (AAD) or colitis. Human patients and animal models with intestinal microbiomes of limited diversity following antimicrobial agent challenge clearly seem to be at increased risk for CDAD or related disorders.^{6,17,52,86} Antimicrobial agents of various classes (cephalosporins, fluoroquinolones) are associated with development of AAD in children and adults and highlight the importance of an intact gut microbiome in resistance to infection by intestinal pathogens.^{73,76} In addition to therapy by specific antimicrobial agents (e.g., metronidazole, vancomycin), microbiome supplementation or replacement by fecal microbiota transplantation (FMT) emphasizes the importance of the intestinal microbial community in resolution of CDAD.^{25,47,62,90} A potential confounder is co-infection with *C. difficile* and other pathogens in cases of AAD.²¹ Enteric infections result in widespread perturbations of the intestinal microbiome highlighted by the phylum Proteobacteria, a phylum that contains many enteric pathogens including *Escherichia*.⁷⁹ Resolution of infection is accompanied by distinct changes in the microbiome, with a greater abundance of the genus *Bacteroides*, as expected. Possibly rapid sequencing of the intestinal microbiome may provide valuable information regarding the condition of the microbiome in the context of undiagnosed enteric infections.

Skin and Vaginal Microbiomes

The structure of the vaginal microbiome varies in pregnancy by gestational age and is characterized by decreased bacterial diversity and species richness.^{2,72} However, the genus *Lactobacillus* persistently maintains prevalence, and certain species including *L. iners*, *L. crispatus*, *L. jensenii*, and *L. johnsonii* have been demonstrated to be enriched during pregnancy.^{2,72} Consequently, the dominant skin microbiota observed on vaginally delivered babies includes *Lactobacillus* spp., as well as *Prevotella*, *Atopobium*, and *Sneathia* species.²⁴ The transmission of the vaginal microbiota to the baby may provide protection against pathogens by occupying niches prior to the development of site-specific communities. In babies delivered via C-section, the lack of exposure to vaginal microbes results in an initial microbial community similar to the mother's skin microbiota, with an abundance of *Staphylococcus* species.²⁴ Premature

infants are also at risk of disturbed initial bacterial colonization, and recent studies suggest that room and isolator surfaces in neonatal intensive care units are a reservoir of colonizing microbes for these infants.¹⁴ This care environment may be detrimental to the health of these preterm newborns because they have an underdeveloped skin barrier that makes them more vulnerable to chemical damage and microbial infections.⁶⁵ However, the infant skin microbiome is dynamic, and the initial differences arising from mode of delivery do not persist as site-specific niches develop in the initial months after birth.¹⁵

The skin is a continuously self-renewing organ that undergoes rapid turnover and expansion during the first years of life. As a result, the infant skin microbiome continuously matures during this time frame, increasing in diversity and abundance.¹⁵ The skin microenvironment varies greatly between infants and adults due to this rapid skin expansion and the distinct composition of infant skin microstructure, which varies in epidermal thickness and cell size.⁸¹ Around 3 months of age, site-specific communities begin to emerge.¹⁵ The skin microbiota consists of both commensal microbes that reestablish after perturbation and transient microbes from the surrounding environment. Distinct niches form on the body based on levels of moisture and sebum, and glands and hair follicles have their own distinct microbiota. The diversity and composition of the bacterial community at these body sites is also affected by intrinsic factors such as age and genetics, as well as by extrinsic factors such as climate and hygiene, leading to large intrapersonal variations in community composition.⁵⁶ The most abundant bacterial phylum colonizing the infant skin is Firmicutes whereas, in contrast, adults are dominated by Actinobacteria.^{15,37,38} Staphylococci (Firmicutes) are abundant in infants under 1 year of age, and certain skin commensals such as *S. epidermidis* may play a protective role against pathogens. *S. epidermidis* has been demonstrated to inhibit colonization and biofilm formation of the opportunistic pathogen *Staphylococcus aureus* by competition and expression of a serine protease.⁴⁹ *S. epidermidis* also secretes small molecules that can activate Toll-like receptor TLR2 signaling and induce antimicrobial peptide expression by keratinocytes, thus enhancing the skin's defense against infection.⁵⁸ *Staphylococcus* species may promote early immune development, but their effect is predicted to decline because their abundance decreases steadily during the first year of life. However, skin barrier function and immune development are significantly affected by early microbial colonization, and microbial exposure may also affect the maturation of the systemic immune system.⁷⁵

Shifts in microbial communities can drive some commensals to become pathogenic under certain circumstances. Although it is considered a commensal organism, *S. epidermidis* is a primary cause of nosocomial infections and can cause disease if barrier integrity is compromised and it is allowed to invade other sites.⁶⁶ Several skin disorders have also been associated with certain members of the microbiota. Atopic dermatitis (AD), or eczema, is a chronic disorder that affects approximately 15% of children in the United States.³⁸ AD is characterized by *S. aureus* colonization on both lesional and nonlesional skin, and it is associated with worsened disease severity in pediatric patients.⁵⁵ *Propionibacterium acnes* is well known for its role in acne vulgaris in teenagers because this species secretes enzymes that injure the tissue lining of the already inflamed pilosebaceous unit.^{28,38} Although infants have limited sebum production, infantile acne begins to appear at the same time that an increase in *Propionibacterium* occurs at age 4 to 6 months.^{15,45} Psoriasis is another chronic skin condition that can occur in children, and lesional skin has been demonstrated to exhibit increased bacterial diversity concurrent with a decrease in prevalence of healthy skin bacteria such as Actinobacteria.³³ These examples highlight how the skin barrier and the dynamic microbial communities that inhabit it are maintained in a delicate balance, the disturbance of which can predispose the host to cutaneous infections and other inflammatory conditions.

SUMMARY

The human microbiome influences human development and resilience in the context of challenges by infectious agents. Special considerations early in life include the unique biology of pregnancy and fetal development, age-dependent changes and differentiation of the microbiome, and the rapid shifts in microbial composition and function occurring with abrupt

dietary changes. Different stages of human development and different body sites will impact microbial composition and function and affect the ability of the microbiome to modulate or prevent pediatric infections. Microbiome science provides opportunities to consider a broad menu of potential pathogens that may be present in the human microbiome prior to infection. More comprehensive diagnostic tests based on microbiome science may provide a complete list of opportunistic pathogens that pose risk of infection in children with cancer, immunodeficiencies, or chronic disease. Mining of the microbiome for bioactive compounds may lead to new microbiome-based therapeutics, and microbial manipulation by probiotics, specialized diets, or FMT may provide additional therapeutic options for diseases of microbial ecology such as CDAD.

Epidemiology and Biostatistics of Infectious Diseases

6

Eugene D. Shapiro • Robert S. Baltimore

Clinicians care for individual patients, each of whom has certain unique problems. Clinicians base their decisions on a panoply of factors that include features of the acute and chronic medical problems of the patients as well as features of both their personalities (e.g., How likely are they to comply with a certain therapeutic regimen? Do they resist conventional medical care?) and their private lives (e.g., Can they afford a certain medication? Are they planning to travel out of the country in the next few days?).

In contrast, epidemiologists study groups of people. They draw conclusions from studies of large numbers of patients and usually base conclusions on probabilities and biostatistical analyses of average (mean) outcomes.

Fortunately, these two approaches—the individualistic approach of the clinician and the probabilistic approach of the classic epidemiologist—are not incompatible. Indeed, each can illuminate the other. So it is that a chapter on epidemiology and biostatistics is included in a clinical textbook of pediatric infectious diseases. The goal of this chapter is not to make the reader an expert in these fields—courses and textbooks are designed for that purpose.^{17,29,31,33,34,58,59,62} Instead, the goal is to summarize how selected key aspects of epidemiology and biostatistics can be applied to understand studies that will improve our ability to evaluate and treat children with infectious diseases. Readers concerned with the epidemiology of a particular infection or syndrome should consult the appropriate chapter.

EPIDEMIOLOGIC STUDIES

Design of Studies

Overview and Definitions

Epidemiologic studies generally are designed to be either descriptive or analytic. In *descriptive* studies, the goal is to describe a population (e.g., the clinical manifestations and prognosis of children with tuberculosis). In *analytic* studies, the goal is to assess associations between two or more variables (e.g., whether children who receive an experimental vaccine are less likely to develop the infection that the vaccine is intended to prevent than are controls). Indeed, analytic studies usually are designed to assess whether a causal association exists among the variables (e.g., Is a vaccine efficacious? Do children who attend daycare centers have a higher risk of acquiring infections caused by certain bacteria or viruses?). Of course, categorizing a study so easily may not be possible. In a study that is primarily descriptive, causal associations within subgroups may be assessed. For instance, in a study of the clinical epidemiology of tuberculosis in children, the investigators may compare the mortality rates of younger children with those of older children or the mortality rates of children with tuberculous meningitis with those of children who have infection at other sites.

Most studies, whether descriptive or analytic, seek to reach conclusions about the particular group that is being assessed (e.g., children with tuberculosis). However, because studying all persons with the condition of interest is not possible, investigators inevitably study a *sample* of persons and hope that the conclusions drawn from studying the sample apply to the entire population of interest (the *target population*). The *validity* of a study refers to the extent to which the results are true (accurate). The extent to which the conclusions drawn from the study sample (e.g., children with tuberculosis at a certain hospital) are valid for the target population (e.g., all children with tuberculosis in the same city) is a measure of the study's *internal validity*. The extent to which the conclusions drawn from the study sample are valid for a less restrictively defined, larger population (e.g., all children with tuberculosis in the United States) is a measure of the study's *external validity*, which also is called its *generalizability*. To ensure that a study is both valid and generalizable, investigators must take steps to protect against a variety of potential biases that may distort the results of a study.

Elements of an Analytic Study

Epidemiologists refer to the major elements of an analytic study as the *exposure* and the *outcome*. The *exposure* is the factor that the investigator hypothesizes is related causally to the outcome of interest. In this context, the term *exposure* is not used in the classic sense of potential contact with an infectious agent; rather, it is any factor (e.g., living at a certain altitude, race, receipt of either a vaccine or a medication, smoking cigarettes) that may be associated causally with the outcome. The *outcome* is the effect (e.g., cancer) that putatively is related causally to the exposure. The putative association may be one in which the exposure either causes or prevents the outcome of interest.

Before the specific type of study is defined, several additional elements of a study must be considered. One is how the *sample* for the study is selected. In general, investigators select a sample of the population either on the basis of exposure (e.g., patients who either received or did not receive a vaccine or who either attend or do not attend group daycare) or on outcome (e.g., patients who either had or did not have pneumococcal bacteremia or patients who either died or survived). Another key element is the *timing* of the study in relation to the timing of exposure and outcome. In studies in which the timing is *historical*, both the exposure and the outcome occurred before the study was initiated (e.g., a case-control study of a vaccine's efficacy in which cases with disease are identified from historical logbooks and antecedent receipt of the vaccine is determined from medical records). Timing may be *concurrent*—that is, both the exposure and the outcome occur after the study is initiated (e.g., a randomized clinical trial of the efficacy of a new antibiotic). Timing also may be *mixed*, a mixture of historical and concurrent (e.g., a study of the current IQ of children who previously had aseptic meningitis).

A final important element of a study is its *direction*. Direction is used to describe the order in which outcome and exposure are assessed.

It may be done in a *forward* direction, from exposure to outcome (e.g., in a clinical trial of a vaccine's efficacy, the exposure [receipt or nonreceipt of the experimental vaccine] occurs first, and the occurrence of the outcome [the infection that the vaccine is designed to prevent] is determined subsequently). Alternatively, a study's direction may be *backward*, from outcome to exposure (e.g., in a case-control study, the outcome [e.g., pneumococcal bacteremia] is determined first, and exposure [e.g., previous receipt of pneumococcal vaccine] is determined subsequently). Alternatively, exposure and outcome may be determined simultaneously (e.g., a survey in which determination of whether subjects have sickle-cell disease and whether they are taking penicillin occurs at the same time). A study's direction can have important implications for inferences about causal associations; for example, even though a strong statistical association may exist between sickle-cell disease and the use of penicillin, concluding that the penicillin caused the sickle-cell disease would be erroneous. Although such an inference obviously is not plausible in this instance, the dangers of making erroneous inferences about causality are very real when exposures and outcomes that are less well understood are studied, and these types of errors have occurred many times in the history of medical research.

Although the terms *prospective* and *retrospective* are used widely, substantial variability exists in how they are applied. The term *prospective* is used to describe studies in which selection of the sample is based on the exposure, in which the timing is concurrent, or in which the direction of the study is forward (from exposure to outcome). The term *retrospective* is used to describe studies in which selection of the sample is based on the outcome, in which the timing is historical, or in which the direction of the study is backward (from outcome to exposure). Referring to the specific elements of the study is preferable to using the terms *prospective* and *retrospective*, which are applied so imprecisely.

Types of Studies

Epidemiologic studies may be classified as either experimental or observational. In *experimental studies*, the exposure is assigned by the investigators (e.g., in a clinical trial of an experimental vaccine, the investigator assigns subjects to receive either the experimental vaccine or a placebo). In *observational studies*, the exposure occurs naturally (e.g., rainfall in a study that assesses the effect of the amount of rainfall on rates of mosquito-borne infections), is selected by the subjects or their parents (e.g., attendance at group daycare in a study that assesses the frequency of infectious illnesses in children who attend and others who do not attend group daycare), or is assigned in the course of regular medical care (e.g., receipt of an approved vaccine in a case-control study of the effectiveness of the vaccine). Observational studies also are called *surveys*.

Experimental Studies

The paradigm for an experimental study is the *randomized clinical trial*, which is a special type of *longitudinal cohort study* in which the exposure is assigned randomly to the subjects by the investigators. In randomized trials, the direction of the study always is forward, selection (or categorization) of subjects always is based on exposure (i.e., exposure is determined at the time of randomization), and timing always is concurrent (both exposure and outcome are determined during the real period of the study). Randomized trials are the sine qua non for evaluating the effect of new agents designed either to prevent (e.g., vaccines, prophylactic drugs) or to treat (e.g., antimicrobial agents) diseases. By randomly allocating subjects to either receive or not receive the agent that is being tested, potential bias is minimized. Theoretically, if the size of the sample is adequate, the only difference between the groups is whether they received the experimental agent. Consequently, if the study is conducted properly, inferring that statistically significant differences in outcomes between the groups were related causally to the experimental agent is reasonable. For this reason, in most instances, the efficacy of new therapeutic agents or new vaccines must be demonstrated in clinical trials before the U.S. Food and Drug Administration (FDA) will approve them (although in some instances new products are approved if criteria for safety and for some surrogate end point, such as a serologic correlate of immunity, are met).

The advantages and disadvantages of randomized trials are summarized in [Box 6.1](#). Although clinical trials are the gold standard for

BOX 6.1 Randomized Clinical Trials**Advantages**

Gold standard for scientific validity
 Randomization ensures unbiased allocation of the exposure (e.g., a new drug or an experimental vaccine)
 Blinding ensures unbiased assessment of outcomes

Disadvantages

Poor statistical power for rare diseases
 Requires large samples
 Requires longitudinal follow-up
 Logistically complex and expensive
 Impaired generalizability when the study population differs from the ultimate target population
 Ethical issues
 Requires informed consent
 Difficult to use to evaluate approved (presumably efficacious) products

investigators who wish to design a scientifically valid study, they do have numerous limitations. A major problem is that clinical trials usually are expensive. Subjects need to be selected, enrolled, and monitored longitudinally to detect the outcomes. When the outcome is a disease that is relatively rare (e.g., pneumococcal bacteremia), large samples are necessary to provide adequate statistical power. Because sponsors of clinical trials usually want to test a new drug or an experimental vaccine under conditions that will maximize the chance that it will be found to be efficacious, patients with comorbid conditions (e.g., sickle-cell disease, asplenia, metastatic cancer) that might negatively affect their response to the new agent often are excluded from the study. If the subjects who are excluded are an important part of the target population for the new agent (e.g., the patients with comorbid conditions are likely to be at high risk for serious complications of the disease and thus potentially could benefit greatly from an effective new intervention), the generalizability of the results of the clinical trial may be impaired.

Most randomized clinical trials are conducted in a *double-blind* manner; that is, neither the investigators nor the subjects know whether they received the experimental intervention (e.g., a new drug) or the comparison agent (e.g., either a placebo or an agent used in the standard manner). Double-blinding helps ensure lack of bias in ascertainment of the outcome because neither the subject nor the investigator can be influenced either to (or not to) seek medical care or undergo diagnostic tests on the basis of which of the interventions was received.

Randomized clinical trials may pose difficult ethical problems because the new (and potentially efficacious) agent is not given to the controls. By the time that clinical trials are begun, usually some evidence suggests that the agent is efficacious (e.g., preliminary studies in a limited group of subjects showing that a new vaccine induces antibodies). Accordingly some patients and patient advocates might suggest that withholding a potentially efficacious therapeutic agent or a vaccine from persons at risk is not ethical; consequently, it may be difficult to have persons agree to be potential controls in studies of a promising new therapy.

Problems also may arise when approval of a product for the target population is based on studies that are conducted in a different population. For example, polyvalent pneumococcal polysaccharide vaccine was approved in the United States for the elderly and for adults with chronic conditions, such as chronic obstructive pulmonary disease and congestive heart failure, that put them at increased risk of acquiring serious pneumococcal infections. However, the data on which approval was based were derived from clinical trials conducted among young gold miners in South Africa who were at risk largely not because of their age or underlying illnesses but because of the conditions in which they lived and worked. Reports of vaccine failure and poor antibody response to the vaccine in the target population in the United States led to questions about the vaccine's efficacy. However, once the vaccine was approved, conducting a randomized clinical trial in the target

population was difficult ethically because it would mean withholding, on a random basis, an approved (and presumably efficacious) vaccine from patients at risk. Consequently all but one of the post-licensure studies of this vaccine's efficacy were observational studies.

Conducting an experimental study in which the exposure is not assigned randomly is possible. For example, one might conduct an experimental cohort study in which volunteers receive a certain intervention (e.g., a new drug) while controls receive no intervention. Both groups would be monitored forward in time while undergoing surveillance for the outcome event. Although such a study incorporates some of the features of a randomized clinical trial, because the intervention is not assigned randomly, such studies are subject to significant biases.

There are also situations in which special kinds of clinical trials are needed. For example, *cluster randomized clinical trials* are now common. In this type of experimental study, the unit of randomization is not the individual but rather a group or "cluster" (e.g., randomization by community). This can be important in trials of, for example, experimental vaccines or other interventions that may induce herd immunity, so that unimmunized individuals in a community in which many individuals received the vaccine may be at lower risk than unimmunized individuals in the general population. However, this type of study also presents special challenges in its design and statistical analysis.⁹ Another special kind of clinical trial is a *noninferiority* or an *equivalence trial*, designed to show that the effectiveness of a new agent is not inferior to a standard agent (by a specified amount) or that its effect is equivalent (with specified parameters). These kinds of trials also present special problems in design and analysis.^{52,60,68}

Observational Studies

Cohort studies. The direction of cohort studies always is forward, and the selection (or categorization) of subjects is always based on exposure; however, the timing may be concurrent, historical, or mixed. Thus, a cohort study may identify a cohort of subjects at a point (or at several points) in time in the recent or remote past, categorize them regarding their status with respect to the exposure (e.g., receipt of either a vaccine or a drug), and then monitor them forward in time for the occurrence of the outcome event (e.g., an infection or an unpleasant complication) until a certain point in time, which could be in the past, present, or future. As in a clinical trial, subjects must not have the outcome at the time of enrollment in the study.

Cohort studies share many of the disadvantages of randomized clinical trials (see Box 6.1) but have the additional disadvantage that, because they are not experimental, they are subject to many potential biases. On the other hand, cohort studies have many practical advantages (e.g., the timing can be historical, so conducting a 30-year follow-up study in just months is possible), and, because they are observational studies, they usually have fewer potential ethical problems than does a randomized trial. In addition, for rare exposures, a critical factor is to be able to base selection of subjects on exposure.

Case-control studies. In both clinical trials and observational cohort studies, the selection of subjects is based on their exposures, and they are monitored in a forward direction until the outcome is determined. In case-control studies, the process is reversed. Subjects are selected on the basis of outcomes. The cases have the outcome, usually a disease; the controls do not have the outcome. The direction of the study is backward—the previous exposure is ascertained after the subjects are selected. The timing of case-control studies usually is historical, but it may be mixed; the timing of the exposure always is historical, but the timing of the outcome may be either historical or concurrent. For example an investigator may conduct a case-control study of a vaccine's effectiveness in which persons who are infected (cases) are identified concurrently through active surveillance of a microbiology laboratory (incident cases). Because case-control studies are nonexperimental and the exposure (and, sometimes, the outcome) occurred in the past, the potential for bias is great both in selection of the sample and in ascertainment of both the exposure and the outcome. The advantages and disadvantages of case-control studies are shown in Box 6.2. Use of "sham" outcomes and/or exposures in addition to the true outcomes or exposures of interest has been suggested as a means of assessing the internal validity of case-control studies.⁶⁵

BOX 6.2 Case-Control Studies

Advantages
Statistically powerful method to assess outcomes that are rare or delayed
Logistically easier and more efficient than large experimental or observational cohort studies
No longitudinal follow-up, so it can be completed relatively quickly and inexpensively
Ethically acceptable because it is an observational study

Disadvantage
Subject to many potential biases

TABLE 6.1 Analysis of Experimental or Observational Cohort Studies

	Outcome Present	Outcome Absent	Total
Exposed	a	b	a + b
Unexposed	c	d	c + d
Total	a + c	b + d	

Risk in exposed subjects: $a/(a + b)$.
Risk in unexposed subjects: $c/(c + d)$.
Relative risk: $(a/a + b) \div (c/c + d)$.
Attributable risk: $(a/a + b) - (c/c + d)$.

Cross-sectional studies. Unlike cohort studies (both experimental and observational), in which timing is forward from exposure to outcome, and case-control studies, in which timing is backward from outcome to exposure, in cross-sectional studies, outcome and exposure are determined at the same time. In cohort studies, causal inference is made from cause to effect, whereas in case-control studies, causal inference is made from effect to cause. In cross-sectional studies, determining whether the exposure preceded the outcome may not be possible. Consequently making valid causal inferences from a cross-sectional study also may not be possible.

Selection of subjects for a cross-sectional study may be based on outcome, exposure, or neither. However, because cross-sectional studies include only persons with prevalent outcomes, they are particularly problematic for studies of infectious diseases because patients whose illnesses (outcomes) either resolved or resulted in death before the study is conducted are not counted as having the outcome. Consequently, cross-sectional studies are more suitable to the study of chronic conditions and rarely are used in studies of infectious diseases.

Analysis of Epidemiologic Studies

The results of epidemiologic studies with dichotomous exposures and outcomes often are displayed in a 2×2 contingency table. However the way that the results are analyzed statistically depends on the type of study.

Cohort Studies

Analysis of longitudinal cohort studies (both experimental trials and observational studies) is shown in Table 6.1. The measure of association between the exposure and the outcome is the *relative risk* (sometimes called the *risk ratio*), which is an expression of the *magnitude* of this association in the study sample and represents an *estimate* of the association in the population from which the study sample was drawn. A relative risk of 1 indicates that no association exists between the exposure and the outcome, a relative risk greater than 1 indicates that the exposure is associated with an increased risk of the outcome, and a relative risk less than 1 indicates that the exposure is associated with a decreased risk of the outcome. The *attributable risk* (the risk of the outcome that is attributable to the exposure) is calculated as the risk in exposed subjects minus the risk in unexposed subjects. Of course, testing the statistical significance of any association is necessary because

the relative risk could be greater than 1 or less than 1 by chance (see later sections on stochastic statistics and confidence intervals).

These analyses assume that no attrition exists among the subjects in the study. However, because of death, migration out of the study area, and loss to follow-up, as well as variation in the time of enrollment (enrollment in either a clinical trial or an observational cohort study may occur over a prolonged period or, indeed, throughout a study), variation virtually always exists among subjects in the duration of time that they are at risk for the outcome. If the average time at risk among the exposed and the unexposed subjects is equal, the analysis shown in Table 6.1 is likely to be valid. However, if a great deal of irregular attrition or new enrollment occurs during the study, the denominator is expressed better as person-time at risk (e.g., person-months, person-years) rather than as the number of persons in the group. When this method is used, the rate then is called the *incidence density rate* and the index of comparison is called the *incidence density ratio*.

In studies of infectious diseases, the outcome event often is the occurrence of an infection. Frequently, persons who become infected recover and may remain at risk for the outcome event again. Nonetheless, a subject usually should be censored (i.e., removed from the study) once the outcome event occurs. The fact that the outcome occurred may indicate that the subject has an increased risk for the outcome, independent of the exposure that is being assessed. For example, consider a study of the protective efficacy of a conjugate pneumococcal vaccine in which one of the subjects (whether the subject is a vaccinee or a control does not matter) experiences three or four episodes of invasive infection caused by pneumococci (perhaps because the subject has a previously unrecognized underlying condition, such as an acquired immunodeficiency syndrome or a congenital immunoglobulin deficiency). The estimate of the vaccine's efficacy would be distorted substantially if each of the outcome events was counted. Generally, in a primary analysis, only the initial event should be counted. Another reason to censor the subject is that, in some instances, the outcome event may be fatal. If some subjects die of the outcome (and, therefore, must be censored), not censoring subjects with the outcome who survive is, in effect, allowing prognosis of the infection to affect the estimate of the vaccine's efficacy on the risk of the outcome event.

Using a different method to adjust for unequal durations of follow-up in a study may be necessary, particularly when a long latent period exists between exposure and outcome (a condition that often is met when the study involves the effect of a potential carcinogen). In such instances, simply to sum the total person-times of exposure may be misleading because the outcome is more likely to occur many years after exposure. For example, although the total person-time at risk would be the same (1000 person-years), the risk of an outcome developing clearly may be substantially different for 500 persons, each of whom is monitored for 2 years after exposure, than it may be for 40 persons, each of whom is monitored for 25 years after exposure. In such situations, the analyses must be adjusted for variation in the length of follow-up, which can be done with the use of *survival analysis* (also known as *life-table analysis*). The two basic methods of survival analysis, the *actuarial* method and the *Kaplan-Meier (product-limit)* method, are described in detail elsewhere.³⁷

Case-Control and Cross-Sectional Studies

Analysis of a case-control study (with dichotomous outcomes and exposures) is shown in Table 6.2. Because selection of subjects is based on their outcomes, one cannot calculate the risk of development of the outcome, as one would in a longitudinal study (such as a clinical trial). Instead, one calculates the proportion of each group (cases and controls) that is exposed. The measure of association in a case-control study is the *odds ratio*. The *odds* of some occurrence is the probability that it will occur divided by the probability that it will not occur. In a case-control study, we are interested in the odds of exposure. The odds ratio is the ratio of the odds of exposure among cases (a/c) divided by the odds of exposure among controls (b/d). For rare events, the odds ratio closely approximates the relative risk of exposure that would be found in a longitudinal study of the same association. Use of a method known as *risk set sampling* allows odds ratios from case-control studies to approximate a risk ratio even if the outcome is not rare.⁴ Cross-sectional

TABLE 6.2 Analysis of Case-Control Studies

	Cases (Outcome Present)	Controls (Outcome Absent)
Exposed	a	b
Unexposed	c	d

Proportion of exposed cases: $a/(a + c)$.

Proportion of exposed controls: $b/(b + d)$.

Odds of exposure among cases: a/c .

Odds of exposure among controls: b/d .

Odds ratio: $(a/c) \div (b/d)$ or $(ad) \div (bc)$.

studies are analyzed either like a case-control study (if the selection of subjects was based on their outcomes) or like a cohort study (if the selection of subjects was based on their exposures).

Summary Statistics

Perhaps the most basic use of statistical analysis is to summarize data. This type of statistical analysis often is called *summary* or *descriptive* statistics. The specific summary measures that are used depend in part on whether the variables being summarized are *continuous* (variables with equal distance between intervals) or *categorical* (variables with two or more discrete categories). Age, weight, height, temperature, concentration of creatinine in serum, and the number of hours spent in group daycare are all examples of continuous variables (sometimes called *dimensional* or *quantitative* variables). Race, sex, country of residence, and whether a patient is being ventilated artificially are examples of categorical variables (sometimes called *discrete* variables). Of course, continuous variables can be analyzed categorically (e.g., age can be divided into either a *dichotomous* variable [<45 years or ≥ 45 years] or a *polychotomous* variable [20 to 44 years, 45 to 59 years, and ≥ 60 years]).

Continuous Variables

A *frequency distribution* is classification of the values of a sample of continuous variables into successive categories (e.g., for a sample of different ages, one might place each value into different 5-year [birth to 4 years, 5 to 9 years, etc.], 3-year [birth to 2 years, 3 to 5 years, etc.], or 1-year [0 year, 1 year, 2 years, 3 years, etc.] categories) and expressed as the frequency of values within each category.

A sample of values of a continuous variable also can be summarized mathematically by describing its central tendency, shape, and spread. The *central tendency* can be expressed as a *mean* (or *average*), a *median* (the middle value of the sample), or a *mode* (the most frequent value in the sample). The mean value is calculated by summing all the individual values in the sample and dividing by the number of individual values. Thus, for a sample that is composed of subjects aged 1, 1, 2, 2, 2, 3, 3, 4, 10, and 12 years, the mean age is 4 years ($40/10$), the median age (the age for which half the subjects are older than and half are younger than its value—if the number of subjects is even, the median is the mean of the two middle values) is 2.5 years $[(2 + 3)/2]$, and the mode is 2 years. These summary measures provide only a limited view of the data. For example, the mean of a distribution can be shifted in the direction of extreme outlying values; in the example, the mean is 4 years even though 70% of the subjects are younger than 4 years. Likewise, from the median value alone, one would not know whether outlying values exist. Consequently, describing the spread of a distribution is important.

The *spread* of a sample may be expressed by its *range* and by its *standard deviation*. The range of a sample is the interval between the highest and lowest value in its distribution. In the previous example, the range is from 1 to 12 years. Another useful way of mathematically summarizing the spread of a distribution is to express the interval between each individual value and the mean value of the sample. To summarize these values, one cannot simply sum all the differences because the sum always equals zero (the sum of the positive differences equals the sum of the negative differences). To avoid this problem, the standard deviation of a sample is used. This parameter is calculated by

FIG. 6.1 Theoretic normal (Gaussian) distribution showing where 1 and 2 standard deviations (SD) above and below the mean would fall. The Greek letter mu (μ) stands for the mean in the theoretic distribution, and the Greek letter sigma (σ) stands for the SD in the theoretic population. In this figure, the area under the curve represents all the observations in the distribution. One SD above and below the mean, shown in dark gray and represented by the distance from point A to point B, is equivalent to 68% of the area under the curve; 68% of the observations in a normal distribution therefore fall within this range. Two SDs above and below the mean, represented by the area under the curve between lines C and D, are equivalent to 95.4% of the area of the curve or 95.4% of the observations in a normal distribution. (From Jekel JF, Elmore JG, Katz DL. *Epidemiology, biostatistics, and preventive medicine*. Philadelphia: WB Saunders; 1996:118.)

taking the square root of the *variance* of the sample. The variance is the sum of the squares of the differences from the mean of each individual value divided by the number of *degrees of freedom* of the sample (which is equal to the number of values in the sample minus one, or $N - 1$). The sum of the squares is divided by the number of degrees of freedom of the sample ($N - 1$) rather than by N (the actual number in the sample) because this calculation is thought to represent more accurately the true variance of the population from which a sample is taken.

To calculate the standard deviation of the sample in the example, one must determine the variance, which is the sum of the squares of the difference of each individual value from the mean of the sample divided by the degrees of freedom (number of values minus one):

$$(2[4 - 1]^2 + 3[4 - 2]^2 + 2[4 - 3]^2 + [4 - 4]^2 + [4 - 10]^2 + [4 - 12]^2) \div (10 - 1)$$

which equals $132 \div 9$, or 14.6667 years. The standard deviation is simply the square root of the variance, which is 3.8297 years.

In the medical literature, investigators often use the *standard error of the mean* (which is the square root of the variance divided by the square root of the number in the sample) to express the spread of the frequency distribution of a sample. However, the standard error actually is designed to be a measure of the standard deviation of the means of repeated samples from a single source population. Because the standard error always is smaller than the standard deviation of a single sample, it gives the erroneous impression that the spread of a sample is smaller than it actually is. A large sample with a large spread (and a large standard deviation) may have a small standard error. The standard error should not be used to describe the spread of a single sample.

The general shape of the frequency distribution can be inferred from the parameters given earlier. The characteristics of the most important distribution in statistics, the familiar bell-shaped curve of the normal distribution, are shown in Fig. 6.1 and are discussed in a later section about diagnostic tests. The peak value of any distribution is the mode. A distribution may be bimodal, trimodal, and so on if it has two or more modes. A frequency distribution may be asymmetric, or *skewed*. If the mean is greater than the median (as in the example), the distribution is skewed to the right; conversely, if the mean is less than the median, the distribution is skewed to the left.

An investigator may want to summarize the relationship between two different continuous variables, which can be done with the use of linear regression, in which a straight line is constructed to represent the relationship between a continuous *dependent variable* (y) and a continuous *independent variable* (x). An equation ($y = a + bx$) can be created that represents the best “fit” to describe the relationship between the actual values of y and x , in which a (the *intercept*) is the value of y when x equals zero and b (the *regression coefficient*) is the slope of the line. Such an equation allows us to summarize the relationship between these variables and to extrapolate the value of each variable for conditions that may not have been observed in the sample. For example, one can calculate the incremental value of y for each interval change in the value of x .

Categorical Variables

The measure generally used to summarize categorical data is called a *rate* or a *proportion*. Rates consist of a numerator and a denominator. The numerator represents the actual number of persons in the sample who have the characteristic of interest (e.g., those with fever, those with tuberculosis, those who received a vaccine), and the denominator is the total number of persons in the sample. The persons in the numerator must be included in the group that the denominator represents, and the persons in the denominator must be able to have the characteristic that the numerator represents. For example, if one were interested in the rate of testicular cancer in the population, women should not be included in the denominator because they cannot have testicular cancer. Some experts believe that rates, by definition, should include a time factor (e.g., incident cases per person-months or per year). However, the term is used widely to refer to a proportion of a sample, as described earlier.

One of the most important rates that is calculated in epidemiologic studies is the *incidence rate* or *attack rate*, which is the number of persons in whom a certain outcome develops divided by the number of persons in whom the outcome could have developed during a specified period. For example, a comparison may be made of the incidence rates of an infection over time in two groups in which the interventions given to prevent an infection differed (e.g., vaccine, placebo).

Another important rate, the *prevalence rate*, is the number of persons in whom a certain outcome develops divided by the total number of persons in the group at a specific point in time. In calculating the incidence rate, persons who at *zero time* (before the study begins) already have the outcome (e.g., prevalent cases) are excluded from both the numerator and the denominator. At time zero, the numerator of the incidence rate is zero. Thus, if one were interested in the incidence rate of lung cancer, persons who had lung cancer at the beginning of the study period would be excluded. The prevalence rate, by contrast, is measured at one point in time, and the numerator includes all persons with the outcome at that time.

Certain features of many infectious diseases affect both the prevalence rate and the incidence rate as measures of the occurrence of disease. The prevalence rate of any condition is related to its chronicity and the mortality rate associated with it; conditions that are common and chronic but are not associated necessarily with immediate mortality (e.g., atherosclerotic heart disease) have a relatively high prevalence rate. On the other hand, the prevalence rates are relatively low for conditions that either have a low mortality rate and resolve completely (e.g., many infectious illnesses) or have a high short-term mortality rate. To get a reliable estimate of the importance of such conditions, one must determine their incidence rates.

To describe variations in occurrence of infections over limited periods within a single population, such as a city or a state, a simple *numerical frequency* (e.g., number of cases of infection) often is used—daily or weekly (during an epidemic), monthly (to reflect seasonal patterns), or annually (to compare successive years). Comparisons among different populations or subgroups within a population or at widely separated times in the same population require use of the *incidence rate*, or *attack rate*.

For infections transmitted by contact, the frequency with which infection or disease occurs among exposed susceptible individuals provides a measure of the infectivity of the agent. This frequency, called the *secondary attack rate*, is defined as the number of contacts who

become infected (or who develop disease) within the maximal incubation period of the infectious agent divided by the number of susceptible persons in the exposed group or population in question. The secondary attack rate is applied most usefully only to closed groups, households, or classrooms, where exposure safely can be presumed for all members. The first, or primary, case is the presumed source of exposure; other initial cases that occur within the minimal incubation period or since presumed exposure of the primary cases are called *co-primary cases*. In calculating the secondary attack rate, primary and co-primary cases are excluded from the numerator and the denominator. Cases that occur subsequently within the maximal incubation period constitute the secondary cases. Cases that develop later are excluded because it is presumed they occurred from either a different exposure or from tertiary spread. The exclusion of immune individuals from the denominator usually is feasible only for diseases sufficiently characteristic clinically that the history serves to identify them (e.g., measles, chickenpox). Moreover, one may not want to exclude immune individuals (who may not be easily identifiable) in calculating primary or secondary attack rates. Although immune individuals are not readily identifiable in the case of common respiratory diseases, the secondary attack rate based on all exposed members of the group still may be a useful measure. Its utility decreases, however, when the period of communicability of the primary case (as with *Mycoplasma pneumoniae* infections) is longer than the incubation period because distinguishing between secondary and tertiary cases becomes difficult.

Finally the occurrence of death caused by a specific disease typically is expressed in two different ways. One, the *cause-specific mortality rate*, is defined as the number of deaths from the disease during a specified period of time divided by the total number of persons in the population. It is a measure of the consequences of the disease in the population. The effect of the disease among infected individuals is reflected by the *case-fatality rate*, which is defined as the number of deaths due to the infection in a specified period of time divided by the number of persons infected during the same period.

Bias

Bias occurs when the estimate of the association between the exposure and the outcome in the sample differs systematically from the true value in the population. Bias in the estimate of the association is different from bias in the measurement of individual variables. The latter bias (which may occur, for example, if an instrument such as a thermometer is calibrated incorrectly) may or may not affect the estimate of association in an epidemiologic study. Biased measurements usually affect the exposed and the unexposed groups equally. By contrast, *analytic bias* is the effect of *differential error* (*nonrandom error*) on the assessment of the relationship between exposure and outcome. Analytic bias can occur because of *information bias* (as a result of differential error in ascertainment of either the exposure or the outcome), *sample distortion bias* (because the joint distribution of the exposure and the outcome in the sample chosen for the study is not representative of the distribution of these factors in the target population), and *confounding bias* (because the joint distribution of one or more variables that independently are related both to the exposure and to the outcome is unequal in the groups that are being compared). Ensuring that bias does not affect a study is critical to its validity. Furthermore, although using statistical methods to adjust for certain sources of bias (particularly for confounding bias) in analysis of the results of a study sometimes is possible, adjustment for bias after the fact may be impossible.

An example of information bias is *detection bias*, which occurs when there is differential detection of the outcome in the exposed and the unexposed groups. For example, numerous studies in which clinical scales to assess whether children with fever have a serious illness have been developed.⁴¹ Often, however, the “serious illness” may include certain abnormal laboratory test results (e.g., an abnormal radiograph of the chest or a low concentration of sodium in serum). Because children with high scores on these scales were more likely to undergo diagnostic tests, detection bias may have occurred because similar abnormalities (e.g., a “silent” pneumonia or a decreased concentration of sodium in serum) might go undetected in the “unexposed” group (children with lower scores on the clinical scale), a much smaller proportion of whom

underwent a diagnostic test to detect a possible outcome. The best way to avoid information bias is to use standardized, consistent methods to ascertain both the exposure and the outcome and to blind subjects and investigators to ensure that no differential ascertainment of either the outcome (in longitudinal studies) or the exposure (in case-control studies) occurs.

Sample distortion bias occurs when the sample in a study is not representative of the target population. However, a nonrepresentative sample does not lead to bias necessarily; bias in assessment of the association between exposure and outcome occurs only if differential distribution of the exposure (or differential risk of the outcome) occurs in the subjects who are selected for the study versus the overall target population. This distribution can be the result of *selection bias*. For example, consider a case-control study of the effectiveness of an approved vaccine in which the control subjects (the uninfected patients) were chosen from private practices in affluent suburbs, whereas the case subjects (the infected patients) were any patients in whom a serious infection developed and who were hospitalized. The association between antecedent vaccination and infection probably is biased because the controls are not a representative sample of the population from which the cases emerged and because the proportion of them likely to have been vaccinated is higher than in the group of all uninfected persons in the population. Another possible source of sample distortion bias is differential loss to follow-up in a longitudinal study. The potential for sample distortion bias can be minimized by maximizing the probability that a representative sample will be selected, ideally by random sampling (or some other kind of unbiased sampling), and by minimizing loss to follow-up in longitudinal studies.

Confounding bias occurs when the association between exposure and outcome is distorted by a variable (a *confounder*) that is distributed unequally between the groups, is associated independently with both the exposure and the outcome, and is not in the causal pathway from exposure to outcome. One example of confounding bias is *susceptibility bias*, which occurs when the risk of the subjects (to development of the outcome) differs in the exposed and unexposed groups, independent of the exposure. For example, imagine a longitudinal study of the protective efficacy of a vaccine against *Haemophilus influenzae* type b in infants. Ensuring that an equal proportion of subjects in the vaccinated and the unvaccinated groups attended group daycare is important because attendance at group daycare is associated with an increased risk of developing infection with *H. influenzae* type b. If a substantially higher proportion of vaccinees than of controls attended group daycare, their attendance might confound assessment of the vaccine's efficacy and result in a biased estimate of the effect of the vaccine (lower than the true effect). By contrast, if a disproportionate number of controls attended group daycare, the estimate of the vaccine's efficacy might be biased in the opposite direction (it would be erroneously high because controls would have a disproportionately higher risk of acquiring infection with *H. influenzae* type b than would vaccinees).

In the previous example, adjusting for the effect of the confounder might be possible by either stratification or multivariable analysis (see later discussion). However, identifying confounders may not always be possible. Random allocation of subjects is the best strategy to protect against confounding, especially if there is uncertainty about the ability to identify all important potential confounders.

CAUSES OF DISEASE

Historical Perspectives

Although the previously discussed principles apply to all epidemiologic studies, in studies of infectious diseases three additional factors contribute uniquely to who is and who is not affected: (1) the cause is a specific external agent (the infecting organism), (2) transmission of the organism to the host is required, and (3) certain host factors, such as immunity to infection or disease or genetic determinants of susceptibility or resistance to infection may affect both risk of and outcome of infection. Recognition of these factors (the infecting agent, transmission, and immunity) evolved gradually over many years.²⁵

The discipline of epidemiology evolved from the study of great epidemic diseases such as plague, cholera, and smallpox. The periodic

waves of these diseases, which were associated with high mortality rates, stimulated the first serious efforts to explain the occurrence of disease on the basis of factors other than supernatural or divine forces.

Fundamental to such explanations was the concept of *contagion*. This factor long had been implicit in attitudes toward victims of leprosy, as exemplified by such early Christian practices as conducting antemortem funerals for lepers, who then were given a bell and cup and forbidden further human contact or, more drastically, were buried alive or burned at the stake.⁵⁷ The English physician Thomas Sydenham (1624–89) introduced laudanum (derived from opium) as a painkiller, recognized the efficacy of Peruvian bark (quinine) in malaria, and revived the Hippocratic idea of “epidemic constitutions” (of atmospheric nature), which, by grafting onto existing illness, gave all concurrent illnesses the character reflecting the then prevailing “constitution.” These views persisted in colonial America, where they were expounded by such eminent individuals as Noah Webster (*Webster's Dictionary*) and Dr. Benjamin Rush of Philadelphia.⁷⁶

Nonetheless, by the mid-18th century, the theory of contagion had gained acceptance for particular diseases, including measles, syphilis, and smallpox. The theory is alleged to have been exploited in an early act of biologic warfare: Massachusetts colonists reportedly presented the blankets of smallpox victims as gifts to the Indians, who then suffered a decimating epidemic.²⁰

The true origin of the concept of immunity is uncertain, but it was applied first in relation to smallpox. *Variolation* (inoculation of people with material from pox lesions that was expected to induce modified, but immunizing, disease) was practiced in the 11th or 12th century in China and in the early 18th century in both England and the American colonies. Also popular in rural England at this time was the theory that cowpox, a minor disease acquired from afflicted cattle, induced immunity to smallpox. This theory was verified by Edward Jenner (reported in 1798) and resulted, years later, in general acceptance of cowpox vaccine (vaccinia) to protect against smallpox.

The germ theory of disease was stated explicitly in 1855 by John Snow, an English anesthesiologist who took up cholera epidemiology as an avocation. Snow argued that the causative agent of cholera was a living cell that multiplied with great rapidity but was too small to be seen under the microscopes then in use.⁷⁰ Louis Pasteur (1822–95) formally validated the germ theory by showing that the microorganisms responsible for fermentation were not generated spontaneously but came from the air.⁴⁷ On this basis, Joseph Lord Lister revolutionized surgery by using carbolic acid to combat atmospheric germs and minimize “putrification” in surgical procedures.⁶⁷

In Pasteur's wake, bacteria were cultured with great frequency from ill individuals and often were identified erroneously as causal agents. Robert Koch (1843–1910), who first isolated the bacterial causes of tuberculosis and cholera, also was the first to introduce scientific rigor into the proof of primary causation. His famed “postulates,” to be satisfied before a causal relationship between a bacterium and a disease could be accepted, required that (1) the presence of the agent be shown in every case by its recovery in pure culture; (2) the agent not be found in cases of other disease; (3) the agent, when isolated, be capable of reproducing the disease in experimental animals; and (4) the agent be recovered in pure culture from such experimental disease.²³

Koch's postulates since have been modified, largely to meet problems posed by viruses. As obligate intracellular parasites, viruses cannot be “cultivated in pure culture.” In addition, they often are host specific and do not produce disease in an animal model. Other considerations that were invoked as elements of proof included the significance of recovery of the agent from diseased tissues, the demonstration of an increase in titer of specific antibody in temporal relation to the disease, and, most conclusive, the specific preventive effect of vaccines containing the viral antigen.²⁸ One further situation not recognized by Koch is that infections with true pathogens do not always cause disease. We now recognize pathogenicity (defined as the proportion of infections that result in disease) as an important characteristic of infectious disease agents.

General Concepts

Causation of infectious diseases is defined in terms of the *primary cause* and *contributing factors* (or secondary causes). The former is the specific

microorganism (the agent of disease) without which the particular disease cannot occur. Contributing factors affect the likelihood that infection will occur and help determine that disease will result, given infection. Identification of the causative agent may lead to the development of effective means for providing specific protective immunization (e.g., diphtheria and tetanus toxoids, vaccines against polio and measles). Finding the cause of a disease also may lead to other means of control. An example is the discovery of *Legionella pneumophila* as the cause of Legionnaires' disease. The discovery of the organism led to the understanding of how the disease is transmitted—via aerosols from cooling towers, which serve as reservoirs for the bacteria.^{16,42} Disinfection of these towers has helped to control Legionnaires' disease.

Infection and *disease* are not synonymous, although infection is necessary for an infectious disease to occur. *Infection* denotes replication of organisms in the tissues of a host, usually with an associated immune response; infection may be either subclinical (asymptomatic), or, if it results in development of overt clinical manifestations, it is denoted as *disease*. There are many examples of infections, such as poliomyelitis, other enteroviral infections, and mumps, that may be either asymptomatic or the cause of serious disease in the host. When disease occurs, it may vary in severity among infected individuals. Some infections produce full-blown disease in all infected susceptible individuals; measles is an example. Simple *colonization*, in contrast to infection and disease, is a state in which the organism parasitizes the host at a given site, replicates, and may persist, but it does not proceed further to cause infection or disease or to induce an immune response in the host. The *carrier state*, in which the organism persists over time and may be transmitted to others, may occur after colonization, infection, or disease. Examples of organisms that behave in this way include group A streptococcus and *Neisseria meningitidis*.

Many factors, largely related to the host and to the conditions of exposure, determine whether colonization occurs and whether the subsequent processes of infection and disease occur. These contributing or risk factors in the host are extensive and varied and may include but are not limited to age, sex, race, immune status, genetic constitution, and general state of health, including underlying diseases. Similarly, contributing factors unrelated to the host may include climate, the presence of vectors, quality of sanitation, intimacy of exposure, and socioeconomic conditions. These contributing factors vary among infectious diseases and are discussed in chapters about specific infectious agents in this textbook.

Factors Related to the Infectious Agent

What characteristics of infectious agents are significant epidemiologically? Factors associated with the occurrence of disease include factors related to perpetuation of the infectious agent, factors that govern the type of contact required to infect humans, and factors that determine the occurrence of disease. Also important are characteristics useful in classification and specific identification of agents. Some important characteristics are *intrinsic*, in that they can be described after appropriate direct examination of the agent. *Host-related* characteristics can be described only on the basis of the behavior of the agents in the host.

Intrinsic Properties

Precise classification and identification of agents are basic to the specific recognition of infections and related disease. Both depend on intrinsic properties, including morphology (which alone provides the basis for identifying most higher organisms), chemical composition (the type of nucleic acid being important in viral classification), and antigenic character, which is related to chemical composition. The last is central to specific identification of agent isolates and antibodies induced by infection. Requirements for growth or replication provide keys to the identification of some bacteria (e.g., fermentation of different sugars) and many viruses that replicate optimally or only in cultures of certain types of cells incubated at specified temperatures. For example, rhinoviruses replicate best in human diploid cells incubated at 33°C.

In recent years, we have gained the ability to rapidly detect and classify many infectious agents by identification of their genomes. The use of whole-genome analysis, molecular analysis of gene fragments, and various methods of polymerase chain reaction (PCR) has resulted

in reclassification of some microorganisms and of rapid identification of pathogens, including microorganisms that cannot be cultivated by conventional means. Developments in this field are shifting the focus of clinical microbiology laboratories from morphologic and biochemical testing to molecular testing.

Several intrinsic properties relate to transmission and long-term survival of infectious agents. Persistence outside the host depends on requirements for replication (viruses replicate only within the cells of their host, whereas bacteria often can grow in food or milk) and on viability under natural conditions of temperature, moisture, and radiation. The ability of agents to persist determines whether transmission requires direct contact, as with influenzaviruses, or can involve indirect mechanisms operating over longer periods. Examples include polioviruses, typhoid bacilli, and the bacteria that cause Legionnaires' disease.

The spectrum of animals and arthropods that an agent can infect (the host range) helps determine the possibilities for the transmission of and the reservoirs for that agent. The broader the range, the greater the possibilities. Agents that are transmitted by arthropod vectors include St. Louis encephalitis virus and *Borrelia burgdorferi*, the cause of Lyme disease. The former can be transmitted by a wide variety of mosquitoes, whereas the latter is transmitted by a limited number of species of ticks. Among agents that do not require a vector, many infect only humans (diphtheria bacillus, the meningococcus, and measles virus), whereas others have multiple natural hosts (rabies virus, most *Salmonella* bacteria).

Elaboration of exotoxins is an intrinsic attribute of many bacteria and in many instances contributes in varying degrees to the pathogenesis of disease and indirectly to immunity. Another factor is susceptibility to chemotherapeutic agents or antibiotics. Successful treatment may shorten the period of communicability, as in group A streptococcal and *Bordetella pertussis* infections, but it may lead to relaxed vigilance for infection; syphilis, gonorrhea, and HIV (since the development of highly active anti-retroviral therapy) are notable examples.

The instability of some intrinsic characteristics as a result of the emergence of genetically different populations because of mutations, selective pressure, transfer of genes or plasmids between bacteria, or genetic recombination can be important. One example is the resistance to chemotherapeutic or antibiotic agents that may result from selective pressure (the probable explanation for the rapid acquisition of multiple antibiotic resistance by gonococci and in human immunodeficiency virus [HIV] or plasmid transfer of resistance to antibiotics among enteric bacteria). Antibiotic resistance is of increasing importance, as exemplified by the appearance of multidrug-resistant *Mycobacterium tuberculosis*, penicillin-resistant pneumococci, methicillin-resistant staphylococci, and carbapenem-resistant *Klebsiella pneumoniae*.¹³

Change in antigenic character can diminish the effectiveness of immunity and complicate specific recognition of infection. Influenza A virus is the classic example, with periodic major changes (*shift*) occurring in either or both crucial surface antigens, hemagglutinin and neuraminidase, associated with pandemic disease and progressive minor changes in hemagglutinin in the interpandemic period. Finally, the emergence of new diseases, such as St. Louis encephalitis, which first affected humans in Paris, Illinois, in 1932, or the appearance of a known disease in a new reservoir, possibly exemplified by the emergence of West Nile virus in North America in the early 2000s, can be the result of adaptation of the agent to a new host.³

Epidemiologic Properties Relating to the Host

Some epidemiologically important properties of infectious agents can be defined only with reference to specific hosts. Such properties include infectivity, pathogenicity, virulence, and immunogenicity.

Infectivity. Infectivity (ability to invade and multiply in a host) is measured conceptually in terms of the minimal number of infective particles required to establish an infection. This number, which can vary from one host to another and within the same host depending on the portal of entry, host age, and, in some cases, medications, can be determined only experimentally. Except for benign agents with which challenge of human volunteers is permissible, the infectivity of agents for humans must be inferred from the facility with which they spread in populations or, more directly, from the frequency with which infection

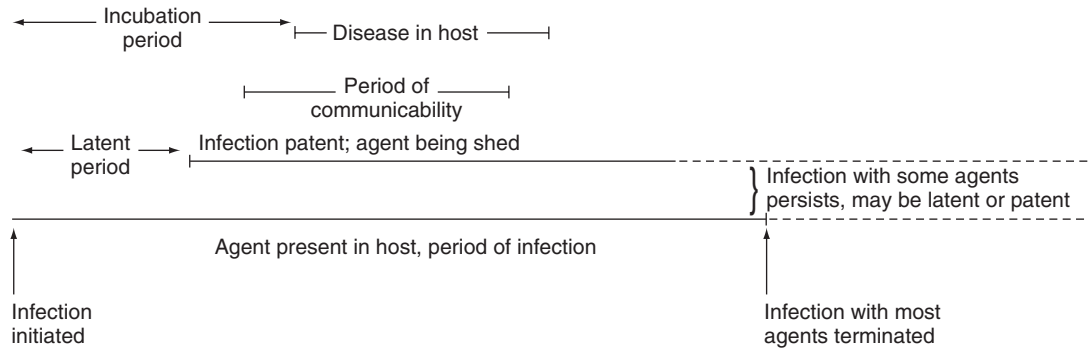

FIG. 6.2 Important phases of infection in vertebrate hosts.

develops in exposed susceptible individuals within a reasonable incubation period (*secondary attack rate*). Some researchers have used prisoners to study infectivity of *Salmonella* and *Shigella*, but the ethics of such studies has now been questioned.³⁸ Measles, varicella, and polioviruses are highly infective because they require few infective particles to cause infection; rubella, mumps, and rhinoviruses have intermediate infectivity; and salmonellae and tubercle bacilli have low infectivity. Infectivity and pathogenicity may vary among strains of the same organism. The infectivity of group A streptococci is related directly to the amount of M protein in the cell wall, and strains of *Staphylococcus aureus* that appear identical in the laboratory may differ strikingly in infectivity and virulence. Additionally, some evidence indicates that strains of influenza A may vary in infectivity and virulence independent of preexisting immunity in the host. Contemporary studies show that variation in certain genes that are not ordinarily expressed in the clinical diagnostic laboratory are responsible for these variations in infectivity.

Pathogenicity. Pathogenicity (ability to induce disease) is measured in terms of the proportion of infections that result in disease. It ordinarily can be determined readily by studies of the incidence and outcome of naturally occurring infections in humans. This proportion may be affected by the size of the infecting dose and numerous host factors, including age. Highly pathogenic agents include typhoid bacilli, rabies, measles, varicella, and rhinoviruses. Agents of intermediate pathogenicity include rubella, mumps, and adenoviruses; polioviruses and the tubercle bacillus have low pathogenicity.

Virulence. Virulence may sometimes be a synonym for *pathogenicity* but is defined more usefully as a measure of the severity of the disease that does occur. Various criteria may be used: days confined to bed, hospitalization rate, serious sequelae that require life support such as dialysis and mechanical ventilation and others such as persisting paralysis, and death. The measure of virulence is the number of severe cases over the total number of cases, which, when death is the criterion, becomes the familiar *case-fatality rate*. With this as our measure, the viral agents previously mentioned fall into a different gradient from that based on pathogenicity. Rabies virus (with a case-fatality rate of nearly 100%) qualifies as highly virulent, and poliovirus (with a case-fatality rate of 7% to 10% for paralytic disease) can be classed as moderately virulent. Measles, with an occasional death from encephalitis or pneumonia, is far down the scale but is still ahead of mumps, varicella, nonfatal rubella, and rhinoviruses, for which the case-fatality rates are very low. Outcomes of severity short of death such as days of intensive care utilization or of requirement for supplemental oxygen can be used in a similar fashion.

Immunogenicity. Immunogenicity (ability to induce specific immunity) is measured best functionally in terms of the degree and duration of resistance conferred by infection. Although agents may differ with respect to the immunogenicity of their intrinsic "protective antigens," more important factors are the sites of primary infection and disease and the amount of antigen formed during infection to stimulate a host response. Superficial sites, such as the respiratory mucosa, are guarded chiefly by secretory antibody, which is poorly persistent; agents such as rhinoviruses, which replicate only at such sites, are ineffective stimulants of the systemic immune response. The amounts of the respective toxins released during clinical tetanus and diphtheria usually do not induce satisfactory

immunity. In contrast, systemic viral infections, such as with measles and yellow fever viruses, induce solid and long-lasting immunity.

Factors Related to Relationship Between Infectious Agent and Host

The infected host provides a shelter in which the agent can multiply and from which it may spread. Key questions involve how long the agent can persist in the host and over what period and by what avenues it can escape. The time relationships and descriptive terms of different phases of infection are suggested schematically in Fig. 6.2.

When the agent is not readily recoverable but perhaps is hidden within host cells or at some other site, infection is termed *latent*. Conversely, when the agent is being shed, as in feces or respiratory secretions, or can be recovered from blood or tissues, infection is said to be *patent*. Infections are necessarily latent at first (the *latent period*) and become patent when the agent has multiplied sufficiently for shedding to begin. The *period of communicability* commonly starts soon after initial shedding begins and continues as long as the level of shedding is sufficient for transmission. The rapidity with which disease is spread is related to the length of the latent period, which almost always is shorter (sometimes much shorter) than the better known *incubation period* (time until disease develops). The period of communicability has no consistent relationship to either the occurrence or the duration of disease.

Persistence in the host is important to the agent for as long as escape remains possible. The period of persistence (see Fig. 6.2) varies widely among agents. Infection terminates completely within 2 to 3 weeks with many agents, such as most respiratory viruses, and after a few months with some agents, such as polioviruses or adenoviruses. Truly persistent lifelong infections may become permanently latent, as with some herpesvirus group (Epstein-Barr virus, cytomegalovirus) infections. Infection may remain permanently patent (approximately 3% of typhoid cases, numerous hepatitis B virus infections), may be intermittently patent (herpes simplex virus infections [HSV]), or, after years of latency, may recrudescence with patency and associated disease (tuberculosis, Brill disease caused by *Rickettsia prowazekii*, varicella zoster virus [herpes zoster]).

Reservoirs of infectious agents. *Reservoir* is defined as any entity (living [e.g., animal or plant] or not [e.g., soil]) in which the infectious agent can survive. The reservoir may also serve as the site from which the agent can be transmitted to living hosts or to vectors. The reservoir may be a continuing chain of transmission from one host to another (including vertebrate and invertebrate species). Chains with long links requiring infrequent transmission are especially favorable to survival of agent species.

Among agents for which humans are the only natural vertebrate host, many contrasting patterns exist. The most common is exemplified by infections with most respiratory viruses, which are characterized by short latent periods (1 to several days) and short periods of communicability (rarely >1 week). The links are short, and frequent transmission is necessary. At the other extreme are long-persisting infections associated with continuous (typhoid carriers, hepatitis B virus, HIV) or intermittent (HSV) *patency* or shedding. The links in this case may be as long as the postinfection life of the host and render generation-to-generation

transmission possible. Such transmission also may occur via congenital infection, as in mice infected with lymphocytic choriomeningitis virus. Examples in humans include cytomegalovirus and hepatitis B virus infections. Long links also occur in persistent infections that, after many years of latency, recrudescence to cause disease and renewed shedding (varicella zoster virus and *R. prowazekii*).

When infection of invertebrate hosts (vectors) is a link in the chain of transmission, a wide range of reservoir patterns is possible. The simplest involves agents for which humans are the only natural vertebrate hosts (malaria parasites, *R. prowazekii*, dengue virus), with the chain consisting of alternating links of human and vector infection. More commonly, the basic reservoir is a similar alternating chain primarily involving lower vertebrate hosts, with humans being an opportunistic and usually blind-end host. Examples include murine typhus rickettsiae and plague bacillus (both cycling primarily in rats and rat fleas), Lyme disease, and various arboviruses (yellow fever, St. Louis encephalitis). In the case of the latter, the broad vertebrate (numerous avian and mammalian species) and invertebrate (various mosquito species) host range results in very complex patterns that in a given area are defined by the prevalent susceptible host species. The links in these chains are defined temporally by the persistence of patent infection in the vertebrate host and the short life span of the invertebrate host.

Several aspects of infection of the invertebrate (vector) host are important. Typically, infection is acquired in a blood meal and endures for (and does not influence) the life span of the arthropod. Hibernating arthropods may be the long link in the chain by which the agent survives the winter. In at least two instances, infection kills the vector: *R. prowazekii* in the body louse and plague bacilli in the rat flea. As with malaria, infection of the arthropod also may permit completion of an essential stage in the developmental cycle of the agent. Finally, transmission of infection from arthropod to arthropod may be alternate or necessary links in the chain. Transovarial transmission of *Rickettsia tsutsugamushi* (scrub typhus) in mites is essential because the individual mite feeds only once, during the larval stage, on vertebrate hosts. Transovarial transmission also occurs in ticks infected with *Rickettsia rickettsii* (Rocky Mountain spotted fever) and in *Aedes triseriatus* mosquitoes infected with La Crosse virus (California encephalitis), in both cases affording an overwintering mechanism. Venereal transmission of La Crosse virus between mosquitoes has also been shown.⁷¹

Finally, the inanimate environment can play a role in the reservoir mechanism. Examples are bacteria that can multiply in the free state (salmonellae and staphylococci in food) and agents endowed with unusual survival capacity (tetanus bacillus and *Histoplasma capsulatum*, both of which form highly resistant spores). It also occurs when a brief sojourn under proper environmental conditions is required for a necessary stage in the life cycle (e.g., hookworm eggs from human feces must hatch into larvae to become infectious).

Mechanisms of transmission. *Transmission*, in this context, is defined as the transport of an agent from one vertebrate host to another. It involves escape from the source host and conveyance to and entry into the recipient host. The basic interdependence of these sequential steps is illustrated in Table 6.3, which also presents specific examples of diseases. Although humans are the usual or only source for most agents of human disease, lower vertebrates serve as the major or only (rabies virus) source for some pathogens.

Fomites are intimate personal articles, such as handkerchiefs, playthings, and eating utensils. *Direct contact* includes not only physical contact (shaking hands, kissing, sexual intercourse) but also, in practice, short-range (within 3 feet), airborne transmission by large droplets (>5 μm) containing hundreds or thousands of organisms that descend rapidly to the ground or floor. These heavy droplets are the primary route of transmission of group A streptococcal pharyngitis,⁷³ pertussis, and influenza.

Indirect transmission for respiratory and some other infections includes the acquisition of organisms from dust (e.g., tubercle bacilli), from fomites (inanimate objects in the environment such as bedding⁵¹), and from airborne droplet nuclei (<5 μm) containing only one or a few organisms that promptly dry, float in the air for long periods, and may be wafted for moderately long distances, and even between rooms or floors in a hospital. Transmission by airborne droplet nuclei is limited to highly infectious agents such as varicella virus. Because respiratory colonization with group A streptococci requires a large inoculum, airborne droplet nuclei play no role in their transmission. Other forms of indirect transmission include inanimate vectors such as food, milk, and water, which are frequent vehicles for spread, particularly of intestinal infections. Another source of indirect transmission is animate vectors, which either may function as a vehicle for transport (as with flies that carry organisms from feces to food) or may be infected. In the latter case, multiplication and transformation in the vector are required for transmission, as with African trypanosomiasis and the tsetse fly.

Conveyance ends when the agent reaches a portal of entry, which to be effective must provide ready access to a tissue in which the pathogen can lodge and multiply. For a given agent, a particular portal (nasal, genital, or oral mucosa) often is obligatory or usual, but alternative portals may be possible. Rhinoviruses replicate only in nasal mucosa, whereas typhus rickettsiae typically enter through skin broken by a louse bite but also can infect via ocular or respiratory mucous membranes.

Factors Related to the Host

Many biologic and behavioral characteristics of the human host influence the occurrence of infection and subsequent disease. Although the host characteristics to be considered are of widely differing nature, they operate by influencing one or more of the following: degree of exposure, innate susceptibility to infection, and the likelihood of specific immunity. Although much of the following discussion focuses on the individual human host, factors that influence individuals also affect whole human populations. A key principle to be emphasized is the usual existence of a gradient of response to exposure to an infectious agent. Because of this gradient, the occurrence of characteristic overt disease is a notably unreliable measure of the extent of activity of a disease agent. Given a particular exposure, infection may not occur, disease may not result, or the consequences may range from trivial to the fully developed syndrome “characteristic” of the agent. Accumulating data indicate that specific host genes may be responsible for differences in host susceptibility.

An inadequate challenge dose, an unsuitable portal of entry, or specific host immunity also may explain failure of infection to develop. Whether infection causes disease and the extent, nature, and outcome of the resulting disease are determined partly by host-related properties

TABLE 6.3 Typical Modes of Transmission From Host, Conveyance, and Portal of Entry

Agent Shed via	How Conveyed	Portal of Entry	Disease Example
Respiratory secretions	Airborne droplets, fomites, or direct contact	Respiratory	Common cold, influenza, respiratory syncytial virus
Feces	Food, fomites, water, flies	Oral	Poliomyelitis, typhoid, rotavirus
Blood	Arthropod vector, transfusion, needle stick	Skin—via insect bite, intravenous device	Typhus, dengue, malaria, human immunodeficiency virus, hepatitis B and C
Lesion exudate	Direct contact, sexual intercourse, fomites, flies	Skin, genital, or ocular mucous membrane	Syphilis, trachoma, staphylococcal abscess
Aerosols	Droplet nuclei, direct inhalation	Respiratory	Tuberculosis, varicella

of the agent (pathogenicity and virulence) and partly by host defense mechanisms, a variety of which confront an infectious agent that has reached a site of primary infection. Bacteria and other extracellular parasites stimulate an inflammatory response at the site that is an effort to localize the invaders by a retaining fibrin network, as well as cytokines that are produced by the host; the invaders are destroyed by congregating numerous phagocytic cells. Invader organisms may meet sinusoidal passages lined by phagocytic cells in regional (lymph nodes) and bloodstream (bone marrow, spleen, and liver) filters. In addition, clinicians are beginning to understand the importance of innate immunity. This complex network of receptors and responders prevents invader microorganisms from gaining access to tissues. In addition to physical barriers already mentioned, the innate immune system includes a family of receptors known as the Toll-like receptors. These recognition molecules signal the host to activate numerous protective mechanisms. Discussion of this system is beyond the scope of this chapter.

Several aspects of the outcome of infection are important, the first being survival of the host. Death is an unsatisfactory outcome not only for the host but also for the many agents for which survival as a species depends on continued transmission by the host. The remaining aspects relate to the surviving host. Was recovery from disease complete, or were permanent sequelae present? If the latter, were they stationary (as in paralysis resulting from polioviruses) or potentially progressive (rheumatic heart disease resulting from streptococcal infection, pulmonary tuberculosis)? Another aspect, persistence of the agent, was discussed previously (see “[Factors Related to Relationship Between Infectious Agent and Host](#)”). The final aspect is the state of postinfection resistance. If it is incomplete, the recovered host may experience reinfection, with or without disease, and may again become a source of infection for others.

Biologic Factors

Biologic factors include characteristics such as age, sex, and race (ethnic group), which are so important and easily ascertained that determining their relationship to occurrence of disease is a usual first step in an epidemiologic description. Biologic factors also include genetic makeup, general health status, and specific immunity.

Age

The influence of age is illustrated best by patterns of common diseases such as varicella, measles, and mumps before the advent of vaccines. All three diseases occur predominantly in young children who are affected because of their usual lack of immunity and their high risk of exposure to other children, among whom most infections occur. Older individuals are likely to be immune and, unless they are parents of young children, are less likely to be exposed to infected individuals. Vaccines that provide only temporary immunity could cause a shift to an older age at presentation in the population.

Age is also often related to the outcome of infections in nonimmune individuals. Demonstration of the influence of age requires that all infections be recognized and classified according to the severity of the resulting disease (if any). When many or most infections are subclinical (as with polioviruses and other enteroviruses), the increase in the case-fatality rate with age is apparent immediately, but special studies to document asymptomatic or mild infections are required to show that the proportion of infections that resulted in clinical disease also increased with age. In contrast, the case-fatality rate for pertussis is highest in young infants. With measles and varicella zoster virus, initial infection at any age usually results in characteristic disease, but the frequency of serious disease increases with age.

Sex, Race, and Ethnicity

That sex may be a factor is illustrated by the fact that most infectious diseases typically occur more frequently in males than females. The question, with respect to any particular disease, is whether these differences between sexes reflect innate differences in susceptibility to disease or can be attributed to sex-associated differences in behavior, occupation, or stress. The increased rate and poorer outcome of infection in male neonates suggests a true biologic difference.

The incidence of many diseases varies greatly among groups defined by race or ethnic group. This variation may be explained by differences

in behavior or environment for which socioeconomic status is a marker. Ethnic groups share many genetically determined traits, however, which may include either heightened susceptibility or increased resistance to specific infectious agents. Selective evolutionary pressure may be invoked to explain the greater resistance of whites to tuberculosis and the heightened resistance of blacks to malaria.¹ Differences in host susceptibility based on race, familial clustering, and ethnicity are being investigated at the genomic level now that the code for the whole human genome has been elucidated. Current investigations are directed at discovering polymorphisms of genes that involve the immune response.

General Health Status

General health status includes the physiologic state, nutritional status, presence of intercurrent disease, and stress. The importance of such factors is commonly accepted in many cases but rarely documented by well-controlled studies. Infancy, during which immune mechanisms are immature, is a period of special vulnerability to many infectious diseases. HSV, enteroviruses, and group B streptococci manifest as disseminated infections in neonates, in marked contrast to their presentation in older individuals. Puberty, associated with rapid growth and change in endocrine balance, is a period of vulnerability to acne and tuberculosis. Pregnancy predisposes to more severe and life-threatening influenza, tuberculosis, paralytic poliomyelitis, and varicella.

Gross protein malnutrition causes definite impairment in the cell-mediated immune response,³² a correspondingly increased susceptibility to bacterial and parasitic infections, and increased morbidity and mortality in many viral infections. Viral infections may depress cell-mediated immunity (and increase susceptibility further) to other concurrent infections. In the developing world, where malnutrition may be epidemic, the consequences of diarrhea, measles, and other respiratory virus infections are many times more devastating. Diarrheal diseases also may be the cause and the consequence of malnutrition. Patients with diabetes are especially vulnerable to bacterial infections; measles and pertussis may reactivate quiescent tuberculosis; and, perhaps of greatest importance, otherwise benign respiratory viral infections, notably influenza, may pave the way for development of serious bacterial pneumonia. Infection with HIV enhances the susceptibility to and severity of tuberculosis, toxoplasmosis, and many other infections.

Finally, stress induced by widely divergent stimuli (including strong emotions, physical exertion, trauma, or excessive heat or cold), according to Selye,⁶³ may operate through a pituitary-adrenocortical hormonal path to decrease resistance to infections. Widely accepted examples include physical exertion, child bearing, and rearing of children as factors predisposing to paralytic poliomyelitis and pregnancy and rapid growth during puberty as causes of reactivation of quiescent tuberculosis. The living conditions and stresses of military training are associated with an increased rate of respiratory tract infections, including invasive meningococcal disease.

Immunity and Immune Response

Immunity and immune response to viruses warrant special attention. Although important in recovery from bacterial infection, antibody response is of questionable significance in viral infections because viruses within cells are inaccessible to antibody, and, by the time antibody appears, many or most susceptible cells have been infected already. Nonetheless, the importance of antibody in viral infections is suggested by the great vulnerability of immunodeficient children to vaccine strains of poliovirus, other enteroviruses, and varicella and by the sometimes beneficial effect of passive immunoprophylaxis in preventing measles and hepatitis B. The benefits of previous experience with viruses can be seen with the decreased severity of rotavirus infections following the first bout of rotavirus and the protection afforded by varicella zoster immunoglobulin in highly vulnerable children.

At its maximum (exemplified by postinfection immunity to measles), protection against infection is virtually absolute. At the other extreme (exemplified by many respiratory viral infections), susceptibility to infection persists or wanes, as with pertussis, although the severity of related disease may be reduced. In most instances, protection seems to be mediated by antibody, but cell-mediated immunity also may be

important. Children with defects in cell-mediated immunity are at particular risk for acquiring infection with varicella, *Pneumocystis carinii*, and otherwise noninvasive fungi.

To the extent that immunity protects the individual against infection or acts to minimize shedding of the agent when infection occurs, an immune host can play little or no part in the spread of an infectious agent in the population. If a sufficient proportion of a population is immune, an agent transmitted via contact cannot spread, and nonimmune members of the population would be spared exposure. The concept of *herd immunity* assumes that a nonimmune individual is protected from a communicable infection by being surrounded by immune individuals. The same concept is now referred to as *cocooning* when referring to protection of young infants in a family. What proportion must be immune to achieve effective herd immunity usually is unknown.²¹ This concept is valid only in homogeneous, randomly mixing populations in which all possible pairs of individuals have the same probability of making effective contact. Although measles vaccine has been used extensively in the United States, outbreaks of measles continue to occur in segments of the population who group together in small communities and fail to accept vaccine; these groups are often defined by beliefs, race, economic status, and social behavior.

Human Behavior

Governed largely by habits of the individual and the customs and culture of groups, human behavior greatly influences exposure to and modes of transmission of infectious agents. Cultural factors also underlie attitudes toward preventive and curative practices.

Water is a potential vehicle for many agents. When commonly imbibed without boiling, as in the United States, community water systems constitute potential channels for transmission that usually are well guarded. Occasional operational failures occur, as exemplified by failure of a water quality-monitoring device in a filtration plant that resulted in an outbreak of *Cryptosporidium* diarrhea affecting an estimated 403,000 individuals in Milwaukee in 1993.³⁹ Foods and milk, especially items that are consumed raw or after minimal cooking, likewise are excellent vehicles for transmission of disease. Well-known examples include trichinosis from undercooked pork; bacterial enteritis from unpasteurized milk; fish tapeworm from raw fish; and various forms of food poisoning caused by bacterial contamination during handling, poor refrigeration, and inadequate cooking. In recent years, outbreaks of hemorrhagic diarrhea caused by *Escherichia coli* O157:H7, sometimes associated with hemolytic-uremic syndrome, have occurred as a result of improperly prepared products of bovine origin, particularly ground beef, but also vegetables and fruits.⁵³

Closely related to water and foods is the disposal of human excreta. Casual defecation near habitations or in or near running water leads to dissemination of enteric pathogens by filth flies and by water. The use of human feces (night soil) to fertilize crops commonly eaten raw, such as strawberries and lettuce, has an obvious similar potential.

Many more individual types of behavior also are important. Infrequent bathing and laundering of clothes favors infestation with body lice. Inadequate clothing increases exposure to arthropod vectors and, as in young children lightly clad for summer weather, facilitates the exchange of feces. Going barefoot provides exposure to hookworm larvae. Hand washing minimizes the role of hands in indirect transmission of enteric (fecal) and respiratory (nasal secretion) pathogens. Rhinovirus infections result from inserting contaminated fingers into the nose and eyes.²⁷ Intimate personal contact such as hand shaking, kissing, and play among young children fosters the spread of a wide variety of agents. Even recreation, such as travel, picnics, and camping, may lead to unusual exposure to infectious agents. Sexual behavior is associated with the transmission of numerous infections, including HIV, syphilis, gonorrhea, group B streptococci, and hepatitis B.

Factors Related to the Environment

The environment in concept embraces all that is external to the individual human host. There are three broad environmental areas: *physical*, which includes geologic and climatologic or meteorologic features; *biologic*, which consists of all flora and fauna and all living microbial pathogens; and *socioeconomic*, which encompasses the interrelationships of humans.

Environmental factors often act through indirect paths, and some have the potential to affect the agent, the host, and the agent–host relationship. Solar radiation is lethal for many pathogens in the free state, helps humans synthesize vitamin D, and can provoke recrudescence of a latent HSV infection and result in recurrent fever blisters. The capacity of humans to modify adverse environmental conditions beneficially is another important factor.

Geographic and Geologic Factors

Spread of infectious agents on a global scale requires their transport, which is influenced by distance alone and by geographic features—mountain ranges, oceans, rivers—that assist or impede travel. The importance of these factors declines as the extent and speed of travel increase, but it remains substantial, especially in developing countries. The minimal effect of geographic barriers in containing highly infective agents is overcome by modern travel, and rapid spread by airline travel is exemplified by epidemics of severe acute respiratory syndrome (SARS), which spread from China throughout the world in a matter of weeks.⁴⁸

The natural paths of travel (including waterways), natural harbors, and the location of mineral deposits help determine where populations concentrate. Water supply, dependent in part on geologic formations, is a factor limiting population size and, together with fossil fuels and mineral deposits, influences the type, extent, and location of industrial development. Soil types vary greatly in their ability to hold and purify water and in their capacity to support vegetation, which influences the type and abundance of animal life. Soil is a determinant of the type and importance of agriculture and a major factor influencing the biologic environment.

Climate

The term *climate* describes the typical annual pattern, along with its seasonal variation, of weather conditions in a specified region. Such conditions (climatologic factors) include solar radiation, temperature, humidity, barometric pressure, winds, precipitation (and drought), and lightning. These factors can affect infectious disease agents directly. Many microbial agents in the free-living state are vulnerable to excessive heat and radiation and uncontrolled drying. The life cycles and reservoir mechanisms of many pathogens, including higher parasites, depend on appropriate temperature and humidity. Maturation and hatching of hookworm larvae from ova deposited in the soil require warmth and reasonable humidity, and the multiplication of malarial parasites and arboviruses in their mosquito vectors and the abundance of the vectors are favored by warm temperatures.

The usual seasonal variation in the incidence of specific infectious diseases suggests important influences of climatologic factors, but how they operate may be hard to determine. Overall, respiratory tract infections occur more frequently in colder months, but within this period (roughly October through mid-May in the Northern Hemisphere) the prevalence of the many respiratory pathogens varies greatly. Rhinoviruses peak in the early fall and spring, and influenza viruses are most active in midwinter. Parainfluenza virus type 1 and 2 infections usually peak in the fall. Increased congregation of people indoors facilitates transmission, and fluctuations in temperature and humidity not only affect the viability of agents in airborne droplet nuclei or on fingers or fomites but also may affect host susceptibility to infection.

Enterically transmitted infections occur most frequently in the warmer months, presumably largely because of season-related changes in host behavior. The outdoor play of scantily clad children facilitates the spread of skin infection and fecally shed agents such as enteroviruses. Rotavirus infections are an exception in that they occur most frequently in colder months. More completely understood are the seasonal patterns of infections spread by arthropod vectors; these patterns reflect seasonal variations in the abundance and activity of the vectors and the various lower vertebrate host species, which together constitute the reservoir mechanisms of the specific infectious agents. Climate overall, as a major determinant of the biologic environment, helps determine the abundance and the particular species of flora and fauna in a given area. In the 2000s, there has been considerable interest in the effects of global warming on rates of infectious diseases.

Longer term changes in climate have been associated with changes in patterns of infection. The hantavirus outbreak in the southwestern United States in 1993 has been attributed to unusually heavy precipitation in the spring of 1993 after 6 years of drought. This precipitation resulted in marked proliferation of the deer mouse population, the reservoir of the virus.⁷⁴

Socioeconomic Conditions

Socioeconomic factors depend on the density and distribution of populations; the available natural resources; the level of social, political, cultural, and scientific development; and, most important, the interrelationships of people. These factors typically affect health by indirect means, and, because they often are interrelated closely, the impact of individual factors is very difficult to determine.

The relationship of population distribution and density to the occurrence of infectious diseases is substantial. Increasing density favors the spread of infectious agents to humans from human and nonhuman sources and the occurrence of related disease and development of immunity. In large and dense populations, agents such as measles virus typically infect in early childhood and persist because a sufficient number of new susceptible individuals are added continuously by birth. In smaller populations, the agents are unable to persist and are reintroduced at unpredictable intervals; as a result, manifestations of “childhood” diseases may be delayed for long periods. Populations of urban and rural areas differ not only in relative density but also in other important ways. Exposure to zoonotic agents, especially agents prevalent in wildlife and livestock, is greater in rural areas, although rats and stray dogs may abound in city slums. Environmental sanitation (protection of water and milk supplies, safe disposal of sewage) often is a personal problem for rural residents but is handled by cooperative effort in wealthier urban populations. In addition, the importance of schools and school buses in facilitating exchange of infectious agents is greater in rural areas, where isolation of farm residents otherwise restricts contact among young children.

The basic population unit is the *household*, membership in which has similar implications for health in rural and urban areas. Family members are similar genetically; share a common diet and economic status; are subject to the same cultural, religious, and educational influences; and are exposed to a common local physical and biologic environment. Most important for contact-transmitted diseases, intra-familial contact is prolonged and increases in intimacy with household crowding. In the winter, many homes are insulated and the windows are closed so that air exchange is poor and exposure to airborne organisms is great. Prolonged contact is especially important for persisting infections such as HSV infection and tuberculosis. Family size, regardless of the degree of crowding, is particularly important for acute infections because it determines the number of potential introducers who bring home infections acquired elsewhere. The likelihood of exposure in early childhood increases with family size. Except for early infancy, a period of special vulnerability to some agents (e.g., respiratory syncytial virus, pertussis), early exposure is beneficial because most resulting infections are less likely to have serious consequences.

A population with a highly developed *social and political structure*, through its capacity for cooperative action, enjoys many advantages that directly or indirectly benefit health, including provision of preventive and curative health services, effective environmental sanitation, and well-developed educational facilities. Education closely relates to personal health practices that are based on understanding what individuals should do to minimize disease hazards. Schools, where the educational process begins, are important factors in the exchange of infectious agents among children, especially agents spread by contact and airborne droplet nuclei. This matter is offset partly by the benefits derived from school-based immunization programs.

Economic status affects the occurrence of diseases indirectly through its relationship to adequacy of housing, nutrition, level of education, sanitation, and availability and use of health services. It is also related closely to occupation, which may be associated with exposure to specific infections, such as Rocky Mountain spotted fever (forest workers and hikers in the south Atlantic coast states) and ornithosis (workers in poultry-processing plants).

Occurrence of Disease in Populations

Patterns of occurrence of disease that are not random but instead reflect the influence of underlying causes (risk factors) not only help predict future occurrence of disease but also provide important clues to understanding causation. Describing the pattern of occurrence of disease begins with definition and classification of disease in the individual so that cases can be identified and counted reliably. The occurrence of disease in defined populations can be expressed quantitatively.

Infection and Disease in the Individual

Epidemiologic interest focuses on the specific etiologic identification of *infection* and *disease*, terms that are not synonyms. Technically, any deviation from normal function or state constitutes *disease*. Because virtually all infections cause at least some deviation from the normal state (e.g., a change in the white blood cell pattern and mobilization of such cells at the site of infection), they cause disease. In practice, many infections result in no clinical evidence of disease and are important to the individual only for the reason that they induce immunity. Because subclinical infections help define the overall pattern of occurrence of infection and often play a significant role in its spread, their recognition is important epidemiologically. Subclinical infections go unrecognized except when healthy individuals are observed for infection in longitudinal or case-control studies.

Only infections resulting in disease usually come to the attention of the medical community. To the extent that they are recognized etiologically, they provide the earliest and most available indicator of the pattern of infection in the population.

With few exceptions, such as measles and chickenpox, typical clinical syndromes are not pathognomonic and require the clinician to develop a differential diagnosis. Basically, clinical manifestations depend more on the site or sites of disease than on the infecting agent. Because the number of possible disease targets in the body is small and the number of potential agents is large, reasonably distinct clinical entities may be caused by any of several agents. Notable examples include “common colds,” approximately 40% of which are caused by rhinoviruses and 60% by any of many other viruses, and aseptic meningitis, which may be caused by such agents as mumps virus, many enteroviruses, or *B. burgdorferi*.

Infection with a specific agent may have several possible clinical outcomes. Infection with polioviruses usually is (perhaps 80%) subclinical but can result in brief febrile illness (approximately 15%), aseptic meningitis (4% to 5%), or classic paralytic disease (<1%). The response to agents with multiple potential targets varies even more widely. Group B Coxsackie viruses can cause such disparate entities as acute upper respiratory tract disease, aseptic meningitis, polio-like paralytic disease, myocarditis, and epidemic pleurodynia (Bornholm disease).

Knowledge of the agents active in the community when a given illness occurs helps narrow the differential diagnosis, but confirming etiologic diagnosis requires laboratory assistance by culturing the agent, direct visualization in specimens, antigen detection, genome identification using molecular techniques, or demonstration of a specific antibody response in tests of “acute” and “convalescent” serum pairs.² The diagnosis is most secure when both approaches suggest infection with the same agent. Although demonstration of the agent in relation to the disease site carries special weight (e.g., in a pharyngeal swab specimen from a respiratory illness), its presence could be the result of preexisting persisting infection unrelated to the current illness. A significant antibody response in paired serum (acute and convalescent) indicates a newly acquired infection.

Infection and Disease in Populations

Sources of information. Many sources provide data regarding the incidence of infectious diseases, including U.S. Vital Statistics, which tabulates only fatal cases; the Centers for Disease Control and Prevention (CDC), which receives reports of specific notifiable diseases from state health departments and summarizes them in the *Morbidity and Mortality Weekly Report*; and state and local health departments. In the absence of a focused surveillance project, these data vary in their completeness by source and by disease because of underreporting, subjects who are not seen, and errors in diagnosis.

Among the different states, reporting requirements vary, and adherence to these requirements by providers also varies. Reporting is most complete for uncommon but characteristic disorders of unusual interest, particularly if they are severe or fatal and require hospitalization, such as rabies, anthrax, trichinosis, plague, and diphtheria. Reporting is enhanced by outbreaks, as with measles, mumps, and classic pertussis in recent years. Some notifiable infections, such as leptospirosis and atypical pertussis in partially immune individuals, often are unrecognized and are underreported. Reporting requirements may change from year to year based on CDC or state interests (e.g., neonatal sepsis and West Nile infection) or concerns about bioterrorism. Another source of data often useful in certain areas is state health department laboratories, which perform specific microbiologic or serologic tests for providers.

Infectious diseases that are not notifiable by law pose a difficult problem. Although necessarily limited in scale, longitudinal studies of defined populations of families have yielded valuable information. Finally, researchers now can use well-designed serosurveys to make reliable estimates of rates of previous infection with agents that induce long-persisting antibody.

International data on the incidence of infectious diseases are less precise except in well-developed countries. For the developing world, the World Health Organization (WHO) and the United Nations International Children's Emergency Fund provide estimates of the incidence of morbidity and mortality from various infectious diseases in different nations based on local reports, which are not always collected systematically. Continuing collection of such data is important for monitoring the effects of the Expanded Program of Immunization, which is directed at controlling the major vaccine-preventable diseases of childhood. More difficult to develop are definitive data about the incidence and causation of the respiratory and diarrheal diseases, which are estimated to kill 6 million children annually in the developing world (approximately 5% of the yearly birth cohort).

For developing these kinds of statistics, it is important to have a definition of disease that is as useful as possible, which means that the sensitivity and specificity of the definition should be so balanced that as many cases of the disease as possible are identified while avoiding the confusion that occurs when other disorders with overlapping manifestations meet criteria that are too nonspecific. A well-known example of a useful definition of disease is the Jones criteria for the diagnosis of rheumatic fever, established in 1944 at the request of the National Research Council in an effort to bring order out of chaos at a time when the disease was a major problem in the civilian and military populations.³⁰ These criteria subsequently have been modified to enhance their specificity by making evidence of a previous group A streptococcal infection a *sine qua non* for the reason that too many cases of polyarthritides of other causes met the original criteria.¹⁸ Recently the Jones Criteria were revised. A less specific set of criteria were developed for areas of the world where acute rheumatic fever is common and the "pretest probability" is greater; a more specific set of criteria were developed for use where acute rheumatic fever is rare and less specific symptoms would be more likely to be due to another cause.²⁴ Similarly, the criteria for the diagnosis of Kawasaki disease were revised more recently to avoid missing some episodes in infants and missing the opportunity to prevent coronary artery aneurysms by using intravenous immunoglobulin.⁴⁴

Recognizing the importance of standardized diagnostic criteria for surveillance of infectious diseases of public health importance, the CDC published in 1990 case definitions for reportable infections.⁷⁵ Optimal use of these criteria and reporting of confirmed and probable cases to the proper authorities are of particular importance currently, when, for a variety of reasons, some formerly well-controlled contagious diseases are becoming recrudescence (e.g., mumps, measles, pertussis). All states mandate reporting contagious diseases of major public health importance, particularly diseases affecting children.

Relating infection and disease to personal characteristics. Multiple characteristics may serve to distinguish one individual from another. Some factors are determined at conception—age, sex, ethnicity, genetic makeup, and birth order. Others, far more numerous, are acquired subsequently. They may be biologic (specific immunity, nutritional state), behavioral (smoking, dietary, recreational habits), or

socioeconomic (occupation, educational level, marital status). Many of these characteristics relate to exposure to infectious agents or to susceptibility or resistance to the effects of such agents and to the occurrence and severity of disease.

Relative usefulness and importance of characteristics. Although almost any potentially relevant characteristic of an individual patient can be identified, it is not useful for purposes of description unless we can estimate how many people in the population also possess the characteristic. From census data or other accessible records, numbers of people in groups defined by age, sex, race, occupation, or marital status can be estimated easily. Special surveys would need to be conducted to estimate the prevalence of specific immunity or possibly significant exposure, such as to household pets.

The importance of personal characteristics to the description of a disease varies in two ways. One is in the degree of association that exists between a characteristic and a specific disease. Age is associated strongly with disease caused by prevalent contagious agents, whereas sex usually is not. The second way is in the independence or relative interdependence of characteristics as variables. Inherent characteristics, such as age, sex, and ethnic origin, are independent of one another, whereas acquired characteristics rarely are. The nature of interpersonal contacts, degree of personal hygiene, and usual forms of recreation are associated closely with age or sex or both. The common interdependence of characteristics means that before making an inference from a particular association, one should explore association with other, possibly correlated, characteristics.

Age patterns. The occurrence of infection and disease generally is related so strongly to age that until possible differences in age distribution are taken into account, differences in occurrence among population subgroups defined by other characteristics cannot be interpreted meaningfully. Age as a characteristic is ascertained easily and reliably for affected individuals and the total membership of the relevant population. Description of the age pattern involves computing a series of *age-specific rates* for sequential age groups, usually defined in intervals of 5 years or multiples thereof (e.g., birth to 4, 5 to 9, 10 to 19). For conditions of pediatric concern, the use of single-year intervals (<1, 1, 2, 3, and 4 years) to cover early childhood may be more informative. In some cases, especially in the first 2 years of life, a breakdown by months of age would be informative.

Affected individuals in an age group form the numerator, and all individuals in the population in that age group serve as the denominator. Rates so computed describe the age profile of immunity at a specified point in time (age-specific antibody prevalence rates), the age profile of new infections or disease (age-specific incidence rates), or the age profile of deaths caused by a disease (disease-specific and age-specific mortality rates). Age-specific incidence rates for acute infectious diseases indicate the risk of disease occurring in each age group and, depending on the disease agent, more or less accurately reflect the underlying age-specific infection rates.

Age adjustment of rates. The need to take age distribution into account when comparing disease in different populations is indicated when (1) the rates vary with age and (2) the distribution of the populations by age differs substantially. From published U.S. mortality data for 1983 and 1984, one can compare pneumonia and influenza mortality rates for Alaska and Florida. During those years, 89 deaths were recorded among 986,000 Alaskans at risk, for an annual mortality rate of 9/100,000. In contrast, in Florida, 4703 deaths occurred from pneumonia and influenza among the 21,792,000 residents at risk for those 2 years, for a rate of 21.6/100,000, nearly 2.5 times that of Alaska. These rates are called *crude mortality rates*. In this instance, these rates are misleading for the reasons that the likelihood of death occurring from pneumonia and influenza increases with age, and the age distributions of the populations of these two states differ markedly. National death rates from these infections are nearly 10-fold greater in people 65 to 74 years of age than in people 55 to 64 years of age. For those years, 17.5% and 3% of the Florida and Alaska populations, respectively, were 65 years or older.

To make a valid comparison of the pneumonia and influenza mortality rates for these two states, one must perform an age adjustment; this is a simple process that can be found in available texts of biostatistics and

epidemiology. Briefly, one determines mortality rates for specific age groups (usually categorized within 5 or 10 years) for the two populations and calculates the deaths that would be expected in a common (or standard) population for the same age groupings by using the age-specific rates of the populations being compared, in this instance those of Alaska and Florida. Summation of these expected deaths permits calculation of the rates that would have occurred in the standard population if the age-specific rates of Alaska applied and if the age-specific rates of Florida applied. In this example, the age-adjusted mortality rate for pneumonia and influenza for Alaska is 35.2/100,000, and that for Florida is 21.8/100,000, nearly the reverse of the crude rates. (The combined population of the two states was used as the standard.)

These age-adjusted rates are not true rates; they are used for comparison. Although often applicable to infectious diseases, age-adjusted rates almost always are required for comparisons of morbidity and mortality from chronic diseases.

Sex patterns. Because sex is a readily ascertained characteristic of the membership of populations, the occurrence of infections and disease in relation to sex is described easily. Its simplest form is the *sex ratio*, or the ratio of cases in males to cases in females. This ratio is meaningful only when, as in childhood, the population is divided approximately equally by sex. Although the number of males exceeds the number of females at birth (106:100), the death rate for males exceeds that for females at all ages (average, 1.5:1). From approximately age 20 years on, females outnumber males, the difference increasing with age, which means that when comparing sex-specific rates, age adjustment must be made, or, better yet, the age profiles for the sexes should be compared directly so that important differences in the contour can be seen.

Ethnic or racial patterns. A third characteristic by which members of the population can be grouped in describing occurrence of disease is race or ethnic origin, the usefulness of which has decreased with the increasing frequency of mixed marriages. The U.S. census classification is based on information collected regarding race and native origin. Individuals of mixed racial parentage are classified by the race of the nonwhite parent or, if both are nonwhite, by that of the father. People of foreign birth are classified by country. Native-born children of foreign-born parents are identified as “foreign stock” and grouped according to parental origin. Census data provide estimates of population subgroups belonging to several “races” (white, black, Native American, Chinese, Japanese) or to “foreign stocks” (including foreign born and first generation). The U.S. Census further asks about ethnicity as a separate category and also separately asks whether the respondent is Hispanic or Latino.

Although controversial currently, this method yields differences in the occurrence of many infections and other diseases among such population subgroups. Knowledge of such differences is useful in case finding and organizing the application of specific preventive measures. Subgroups defined by ethnicity possess some similarity in genetic constitution that may determine susceptibility or resistance to specific agents. They also may be affected distinctively by environmental factors because of voluntary or involuntary differences in behavior and patterns of living.

Disease patterns in kinships. Genetically determined susceptibility and resistance to specific infectious agents have not yet been associated clearly with recognized genetic markers that could serve as a basis for defining population subgroups. Most efforts to look for genetic influences have been studies of occurrence of diseases in individuals of differing degrees of relationship within kinships or in the total memberships of different kinships. With rapid advancement in the database of the human genome, considerable interest has been generated in polymorphisms at loci that may define susceptibility to infectious diseases on a genetic basis. Populations with a high prevalence of certain alleles and known to have an increased risk of certain infections could be studied to determine whether the risk is due to abnormal function of the specified gene.

Family episodes of infection and disease. With respect to contact-transmitted infectious diseases, the family is more important as the basic epidemiologic subgroup of a population than for its shared genes. Observation of family units for episodes of infection and related illnesses has contributed significantly to knowledge of the epidemiology of widely

prevalent infectious agents. The situation in all family studies begins with one member's infection, acquired from outside the house. That member then exposes the other family members. The introductory infection and any infections in family members who are exposed constitute a *family episode*, which is described basically in terms of the times of onset of the related infections and the identities (age, sex, position in the family) of the introducer and the infected and uninfected contacts.

Analysis of cumulated episodes of common respiratory illness, observed in the early studies, identified children as the most frequent introducers (important in community spread). Analysis also yielded estimates of the risk of cross-infection occurring within the family, expressed in terms of secondary attack rates among specified members (e.g., younger children) exposed to specified introducers (e.g., a school-child or a parent). Generally, the risk in contacts was related inversely to age overall, as a result of the influence of immunity, and to intimacy of within-family contact (ready exchange between spouses and between children nearest in age). Finally, the relationship of time between the onset of illness in the introducer and onset in family members exposed serves to define the range of incubation periods.

Analysis of the episodes can yield additional information concerning such crucial aspects as mode and duration of the agent's shedding; the spectrum of clinical response to infection, including the proportion that is subclinical; and the significance of previous immunity in the presence of close exposure, as measured by the frequency and clinical consequences of the reinfections that result. The results of the analysis of adenovirus episodes in the Virus Watch program are illustrative.²² Virus appears regularly in the feces and less often (approximately 50%) in the pharynx, and shedding may be abortive (a few days only) or continue intermittently for many months. Overall, 50% of infections are subclinical, and illness, typically febrile and respiratory, occurs more commonly with pharyngeal excretion (65%) than with only fecal shedding (31%). Immunity is 85% protective against infection; reinfections that do occur usually are subclinical. Young children and especially infants younger than 2 years of age are the usual introducers, and within-family spread depends more on duration than on the mode of virus excretion by the introducer.

Socioeconomic patterns. *Socioeconomic status* covers a complex of characteristics, including levels of education and income and, less tangibly, “social standing.” The problem is to discover a useful single indicator. One possibility is area of residence as classified by median income or measures that reflect housing standards, such as type of plumbing and average number of individuals per room. Relevant data are available for census tracts, which have proved useful when the tracts are homogeneous.

Occupation of the head of a household seems to be the one attribute most closely reflecting socioeconomic status. On this basis, the British have defined five broad social classes that directly apply to employed adults and can be extended to cover their dependents. These classes, in descending order, are professional, intermediate, skilled, partly skilled, and unskilled occupations. For use in the United States, based on census-recorded occupations, these terms have been translated as follows:

- Professional workers
- Non-farm technical, administrative, and managerial workers
- Clerical, sales, and skilled workers
- Semiskilled workers
- Non-farm laborers
- Farm workers of whatever level are included in a sixth group as agricultural workers

Relating Infection and Disease to Place

Place is of interest epidemiologically when occupied by humans and, unless indicated as relating to work, recreation, or travel, refers here to residence. Place usually is classified geographically (hemisphere, continent, nation) but also can be classified usefully by environmental characteristics such as climate, altitude, stage of economic development, population density, and urban or rural nature. Variations in occurrence of disease with place reflect parallel variations in the operation of causative factors and raise the question of whether these factors are to be found in the characteristics of the physical and biologic environment inherent to

the place or in the characteristics of the inhabitants. The former is suggested when the age-adjusted risk of disease increases for immigrants and decreases for emigrants, when risk does not vary among the ethnic groups present, and when similar ethnic groups in other places enjoy a lower risk. One also must consider possible differences in reliability and completeness of recognition and reporting of disease.

Global variation. On the global scale, the WHO collects and publishes information concerning the occurrences of diseases derived from statistics compiled routinely within nations for morbidity from notifiable infectious diseases and for causes of death. The great variations among nations in the quality and availability of medical care and other health services result in corresponding variations in the reliability and completeness of the data collected by the WHO. Generally basic demographic data and the quality and availability of health services are equally good in well-developed countries, so specific disease rates can be compared. In less developed countries, demographic data may be inaccurate and medical services may be inconsistent in quality and concentrated in urban populations, within which their availability varies with economic status. Many illnesses and deaths are unattended medically, especially in rural areas, and births commonly are attended by midwives. Because infant deaths are reported more completely than births are, infant mortality rates may be unreliable.

With respect to infectious and parasitic diseases, knowledge of the frequency of disease is less important than is qualitative knowledge of the distribution and spread of disease. Such knowledge guides the application and enforcement of international control measures and is the basis for advice given by physicians to prospective foreign travelers. Important diseases, such as yellow fever, plague, and cholera, because of their high case-fatality rate and characteristic clinical picture, are almost certain to come to attention when substantial numbers of cases occur. Such knowledge may not be publicized, however, or may not be promptly available. Some countries, in the hope that a new outbreak (perhaps of cholera) will be controlled soon, may withhold information to avoid discouraging economically important tourists.

Two additional considerations are relevant to evaluating the disease hazards of foreign travel. One is the fact that recognized occurrence of disease in the indigenous population may be an inaccurate index of risk to a newcomer. Particular agents, such as polioviruses in the past and hepatitis A virus and Epstein-Barr virus at present, may be so prevalent that infections in natives occur so early in life that they usually are subclinical. The second consideration is the nature of the proposed travel. The usual tourist or business traveler visits chiefly larger population centers and popular tourist attractions, where the most important hazards are pathogens transmitted by food or water. Travelers whose activities bring them into more intimate contact with the people and the biologic environment (Peace Corps workers, global health researchers, military personnel) may encounter additional hazards, such as rabies and the locally prevalent arthropod-transmitted pathogens.

As suggested in considering geographic influences on occurrence of disease, the distribution of many diseases is influenced by relevant environmental factors rather than political boundaries. In depicting (or predicting) the global distribution of a particular disease, identifying regions defined by the presence of factors thought to be important to disease occurrence is useful.

For most agents pathogenic for humans, the chief environmental requisite is a susceptible human population, and most such agents already exist wherever the size and density of the population are sufficient for them to persist. Concern about global spread is limited to a few important pathogens, such as *Vibrio cholerae* (cholera) and the influenzavirus. Cholera is a special case in that its spread also depends on poor sanitation. Recent experience in Haiti demonstrated that transmission of this agent can occur by having disaster aid workers from foreign countries introduce cholera, which can then spread because sanitation is poor.¹⁴ Neither persistence nor even limited spread should occur after its introduction into highly developed areas. Influenza A virus continues to be a major and so far unstoppable threat by virtue of its ability to emerge at irregular intervals in a new antigenic coat that largely negates the preexisting widespread immunity.

Local patterns of infection and disease. “Local” units of population for which demographic data are readily available in the United States include

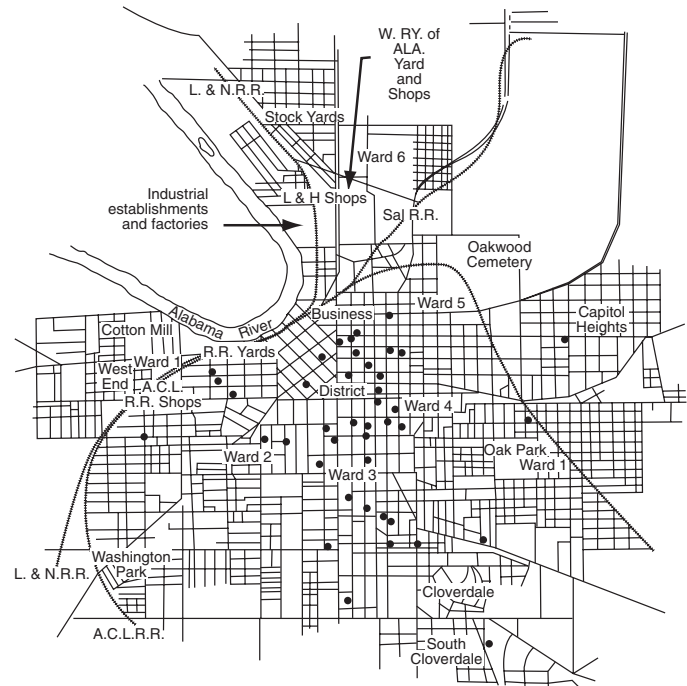

FIG. 6.3 Cases of mild typhus (Brill disease) in Montgomery, Alabama, 1922–25, recorded according to residence. (From Maxcy KF. An epidemiological study of endemic typhus [Brill disease] in the southeastern United States. *Public Health Rep.* 1926;41:2967–95.)

“large” units, such as counties, metropolitan areas, and large cities, which contain smaller units (smaller cities and towns [within counties] and census tracts [within metropolitan areas and large cities]). The smaller units, including unincorporated areas within counties, often can be characterized by variables (urban or rural nature, population density, socioeconomic status, racial or ethnic group) that may help explain observed differences in the occurrence of specific infections and related diseases.

Particularly in relation to outbreaks of acute infectious diseases, spot maps commonly are used to show the local distribution of individual cases. Placing new pins (a different color each week) to mark the residences of newly reported cases serves to visualize the outbreak’s geographic progression. The final distribution of the pins may help identify a major source of infection. A classic example is the 1854 outbreak of cholera in the Golden Square district of London, in which the clustering of residences of fatal cases helped Snow incriminate the Broad Street pump as the source.⁷⁰ Sometimes, place of work is a better guide to the source of infection than place of residence. In another classic study, that of endemic typhus in Montgomery, Alabama, in the early 1920s, the residences of cases (Fig. 6.3) were scattered widely, whereas the workplaces (Fig. 6.4) were concentrated in relation to feed stores and food-handling businesses, all heavily rat infested. This finding led Maxcy⁴⁰ to perform studies showing the basic role of rats and rat fleas in this disease.

Temporal Patterns of Infection and Disease

Definitions. The unit of time used can vary from hours to decades to centuries. In describing acute outbreaks, the units are short—hours for food poisoning, days or weeks for most infectious diseases—whereas long-term time trends are described in longer units of years or decades. Comparisons extending over 1 or more decades may be complicated by changes in diagnostic standards and reporting.

Finally, the meanings of two words commonly used to describe the occurrence of disease over time in a given area should be defined clearly. *Endemic* refers to diseases regularly present. The usual frequency, including expected seasonal variations, is called the *endemic level*. The term *epidemic* applies to any number of cases, small or large, that is a

significant increase over the usual, or endemic, level (although just what constitutes a “significant increase” is not clearly defined).

This principle underlies the monitoring of many infectious diseases, deaths, and pneumonia caused by influenza by the CDC. Such monitoring is illustrated in Fig. 6.5, in which the weekly ratios of deaths caused by pneumonia and influenza to the total deaths observed from 2011 to

2015 are compared with the ratios expected from use of the time series method¹⁵ and the “epidemic threshold,” which depicts the upper 95% confidence limit. When the observed value exceeds the expected one (an increase of 1.645 standard deviations from the seasonal baseline) for 2 successive weeks, an influenza epidemic is indicated. On this basis, epidemics began in approximately the first week of 2013, 2014, and 2015.

In practice, especially at the local level, health authorities use the term *outbreak*, rather than *epidemic* (unless the number of cases is very large), to minimize public alarm. The term *pandemic* is used to describe excess disease occurring in many countries, as influenza did in 1957, 1968, and 2009.

Time clusters. Time clusters relate to the recognition and interpretation of events (infections and disease) that occur with some increased frequency within a limited period or clustering in time. An important determinant of clustering of infections is the incubation period. Infection resulting from a known exposure is manifested within a predictable range of time by the initiation of shedding of the agent and the onset of disease (if it occurs). Although the average incubation period of a given disease is remarkably constant, the usual range broadens as the incubation period increases. This range can be estimated by accumulating cases for which the time of exposure is known precisely or approximately and, with this point as day 0 on the time axis, plotting the day of onset of each subsequent case. The width of the resulting cluster provides an estimate of the range of the incubation period. The best estimate is obtained by using only cases with single, clearly timed exposure, such as when contact with the source case occurred only once, as during a playmate’s birthday party.

A more readily obtained but less precise estimate is that derived from the cumulative analysis of family episodes of a disease based on the assumption that the initial or primary case is the source of subsequent disease in family contacts. Because the primary case is infectious for several days, on any of which effective exposure may occur, the onset of secondary cases would cluster over a range that theoretically may reflect the true range plus the period of infectivity of the primary case.

Knowledge of the range of incubation periods has several practical implications. For contagious diseases, it can be used to distinguish true secondary cases that occur in families from others arising as a result of extrafamilial sources (cases with onset too soon after that of the

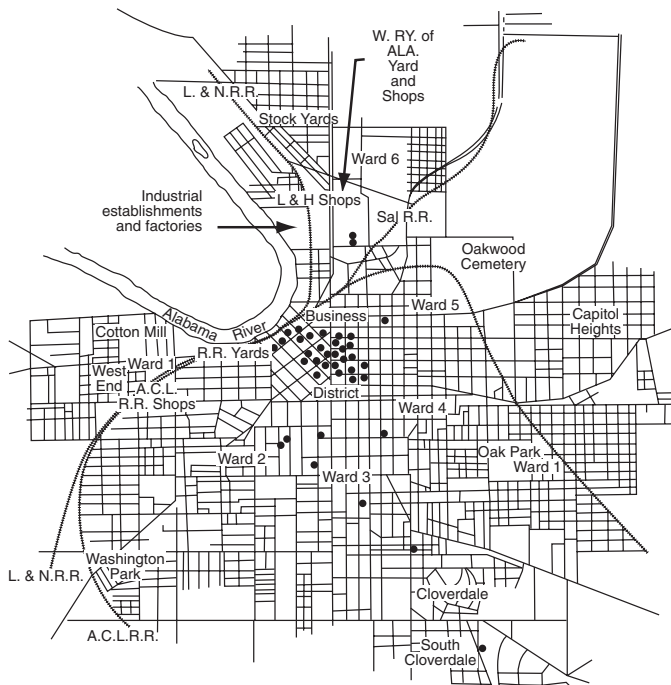

FIG. 6.4 Cases of mild typhus (Brill disease) in Montgomery, Alabama, 1922–25, recorded according to place of employment or, if unemployed, according to place of residence. (From Maxcy KF. An epidemiological study of endemic typhus [Brill disease] in the southeastern United States. *Public Health Rep.* 1926;41:2967–95.)

PNEUMONIA AND INFLUENZA MORTALITY FROM
THE NATIONAL CENTER FOR HEALTH STATISTICS MORTALITY SURVEILLANCE SYSTEM
Data through the week ending October 31, 2015, as of November 19, 2015

FIG. 6.5 Percentage of all deaths attributed to pneumonia and influenza reported by the 122 Cities Mortality Reporting System, by week and year—United States, week ending October 31, 2015. I, Influenza; P, pneumonia. (From Centers for Disease Control and Prevention. Available at <http://www.cdc.gov/flu/weekly/>.)

primary case are called *co-primary cases*) or representing a second generation of spread within the family (i.e., *tertiary cases*). Knowledge of the range of incubation periods also determines the length of time after known exposure that contacts should be observed or possibly held in quarantine for the subsequent development of disease. For poorly contagious diseases, such as typhoid fever, or for noncontagious diseases, such as food poisoning, the distribution of onset in an outbreak can be used to distinguish between “point” epidemics (common time and place of exposure) and outbreaks reflecting exposure to a possibly continuing source. In the former case, onset would fall within the usual range of incubation periods. When the point source is not obvious, investigation can be focused on the interval defined by subtracting the shortest incubation period from the date of onset of the first case and the longest period from the date of onset of the last case.

Short-term patterns

Epidemics. “Point” epidemics have a duration limited by the range of the period of incubation of the particular disease because no secondary spread of the agents occurs. Much more commonly, outbreaks or epidemics extend over longer periods. On the basis of the causative agents and the mechanisms of transmission, three distinct types can be recognized.

The first type typically consists of outbreaks of poorly contagious or noncontagious diseases; such outbreaks reflect the new but persisting activity of a source that must be identified and terminated quickly. One example of such a “continuing source” type of outbreak was a community-wide outbreak of salmonellosis in Madera, California, in 1965, which was traced quickly to the water supply.⁵⁵ Unrecognized typhoid carriers working as food handlers and shellfish harvested from sewage-polluted waters contaminated with hepatitis A virus are other examples of outbreaks requiring prompt epidemiologic investigation to identify the source. One of the major causes of point epidemics is food contaminated with *E. coli* O157:H7. More recent outbreaks, such as the contamination of spinach at the growing source, have been reported by the CDC.¹¹ Often the CDC posts interim reports of investigations on its website (www.cdc.gov) before publication in *Morbidity and Mortality Weekly Reports*.

The element of contagion distinguishes the second type of epidemic, in which disease spreads from person to person. Such epidemics generally are self-limited, and the curve describing them often resembles the bell-shaped curve of a normal distribution. Modification of this curve, as in an abrupt decline from the peak, is the expected result of successful efforts to control the epidemic.⁴³ Epidemics of contagious diseases occur when the population in which the agent persists or is newly introduced contains a sufficient number of susceptible individuals with contact with one another that is adequate to permit transfer of infection from each new case to, on average, more than one susceptible individual. When this average falls below 1, the curve declines, and when the probability of successful transfer of infection approaches zero, the epidemic stops (typically well before the supply of susceptible individuals has been exhausted).

Reasons that underlie this decline and termination of transmission include seasonal changes in environmental factors that affect viability of the agent, such as temperature and humidity; changes in the behavior of hosts that affect the intimacy of contact, such as indoor school versus outdoor play; and the progressive conversion of individuals from susceptible to immune. Institution of appropriate hygienic precautions likely was an important facet of control and termination of the worldwide outbreak of SARS in 2003.¹⁰ Institution of an intensive vaccination program may also reduce transmission and abort an outbreak. If one assumes constant units on the time axis, the slope of the ascending limb of the epidemic curve is determined by the incubation period (interval between successive cases) and by factors that influence transmission (infectivity of the agent, frequency of adequate contact between susceptible individuals). In the absence of effective control measures, the duration of epidemics of a particular disease depends on the size of the susceptible population and the persistence of favorable environmental factors.

Epidemics of “diseases in nature” constitute the third type. Because susceptible individuals usually are abundant in the human population, these epidemics typically reflect increases in the number of sources of

infection in nature. With zoonoses such as arbovirus encephalitis, the initiation, slope of the curve, and duration of the epidemic are determined by the number of susceptible lower vertebrate hosts, the seasonally determined abundance of the vector mosquitoes, and the length of the extrinsic incubation period in the vector. The occurrence of West Nile virus in the United States, which began in August 1999 and has continued with outbreaks in the late summer of each succeeding year in mosquitoes and humans, is an example.^{3,12}

Seasonal and cyclic variations. Predictable periodic variations in disease take two forms, seasonal and cyclic, neither of which is understood completely in the case of agents infecting only humans. *Seasonal* variations presumably reflect the influence of changes in temperature, precipitation, and length of daylight on the activity of the agent. This variation is readily apparent with respect to diseases, such as Lyme disease (the peak incidence of which typically occurs in the summer months), which depend on lower vertebrate hosts and arthropod vectors, the abundance and activity of which are determined seasonally. Similarly, the increased occurrence of enteric bacterial infections (spread by indirect means) in the warmer months is explainable largely by more rapid bacterial growth in unrefrigerated milk and food, the increase in abundance of flies, and the lack of sanitary precautions associated with summer recreational activities such as private swimming pools and unattended foods.

The mode of transmission is only a partial determinant of the seasonal pattern. Although the enteroviruses (including poliovirus), the rotaviruses that cause acute gastroenteritis, and hepatitis A virus all are spread chiefly by fecal-oral mechanisms (direct and indirect), the seasonal patterns are distinctly different (late summer and fall for enteroviruses and late winter for rotaviruses and hepatitis A virus). Similarly, although infections with agents present in respiratory secretions and spread by either airborne mechanisms or contaminated fomites occur infrequently in the summer, their seasonal peaks occur at significantly different times. The season of respiratory diseases coincides roughly with the school year. Infections with rhinoviruses occur most frequently in the early fall and late spring, and infections with parainfluenza virus types 1 and 2 occur most frequently in the fall. The annual peaks of RSV vary among fall, winter, and spring. Mumps peaks in late fall, influenza in late winter or early spring, and measles typically in the spring.

Plotting variation over a series of years reveals a roughly regular cyclic variation for some diseases. In larger metropolitan areas, the usual biennial measles epidemic appears as an enlarged annual wave. Before 1950, deaths caused by meningococcal meningitis occurred on a nationwide basis in cycles of 7 to 9 years, a phenomenon presumably terminated by the advent of prophylactic antibiotics. Pandemic influenza A, which provides the most dramatic example of cycling, is explainable by a major change in the antigenic character of the agent.

Long-term trends. Except for poliomyelitis during the first half of the 20th century, clearly defined long-term trends in the occurrence of infectious diseases in the United States usually have been downward, and in no case has description or understanding of the mechanisms posed a major difficulty. In the case of poliomyelitis, the increase in the rate of paralytic disease that began about 1880 is attributable to numerous factors, including improved sanitation, which resulted in an expanding proportion of infection occurring among older children and young adults without previous exposure to the viruses. In young infants, most poliovirus infections are benign but produce long-lasting immunity; the older an individual is when infected, the more likely that individual will have paralysis. The frequency of paralytic poliomyelitis is related inversely to the level of sanitation. In the United States, the increase in paralytic disease with epidemics of polio continued unabated (with an apparent sharp increase around 1940 because of changes in reporting criteria) until the widespread use of polio vaccines.

The post-1955 decline in poliomyelitis; the much earlier decline in pertussis and diphtheria; the disappearance of smallpox; and the more recent marked decline in measles, rubella, *H. influenzae* type b, and varicella all are attributable chiefly to widespread use of effective specific vaccines. Similarly, the disappearance of indigenous malaria and the decline of rabies to a negligible level in humans in certain areas reflect the application of a variety of effective control measures. Unfortunately, with the exception of smallpox, these measures are not permanent, and

loss of infrastructure for delivery of vaccines or of environmental controls will cause a recrudescence of disease.

Emerging infections. Although in the 1980s one might have said that most infectious disorders had been explored thoroughly epidemiologically and that little was left to do, this clearly is not the case. Infectious disease epidemiology has become increasingly challenging, and in many ways the problems are more complex and necessitate greater cooperation with additional disciplines, such as microbiology and molecular biology.

In part this increased complexity is due to so-called emerging infections, a term that has come into vogue in recent years and refers to two different groups of disorders. The first is associated with the appearance of previously unrecognized or possibly heretofore nonexistent infections in humans. Well-known examples are legionellosis, hantavirus pulmonary disease, acquired immunodeficiency syndrome, Lyme disease, hemorrhagic colitis caused by *E. coli* O157:H7, and Ebola virus infection. The other group includes previously recognized human infections that exhibit changes in epidemiologic behavior or biologic characteristics that enhance their transmission or virulence. These changes usually can be attributed to external influences, such as altered demographics including increasing population and rural-urban migration, international travel, new technology or technologic failure, changes in land use, adaptation of infecting organisms to various influences, and inadequate or underused public health measures.³⁶ To this list should be added changes in host factors such as immune defenses.

No clear dividing line exists between new infections and old ones that exhibit new behavior. Examples of some with new behavior include multidrug-resistant tuberculosis, penicillin-resistant pneumococcal infections, invasive group A streptococcal (popularly known as flesh-eating bacteria) infections, staphylococcal toxic shock syndrome, community-acquired methicillin-resistant staphylococcal infections, H5N1 influenza ("bird flu"), cryptosporidiosis, and numerous infections that are fostered by immunosuppression or various therapeutic measures such as antibiotics and catheters.

These emerging infections are not minor threats. Although in some instances small populations have been affected to date, the potential for widespread disease of epidemic or even of pandemic proportions exists. This potential can be expected to increase because the demographic and other conditions that have predisposed to the emergence of these infections continue to grow and intensify. Maximal efforts must be expended to reverse this process. To achieve this goal requires worldwide collaborative effort among various disciplines, including epidemiology, microbiology, entomology, immunology, clinical medicine, demography, nutrition, sanitation, and even political science.

The responsibilities of epidemiologists regarding emerging infections may be described in three categories. The first category is surveillance, including recognition of the appearance of a previously unrecognized infection or a new variant of an existing disease. Optimal surveillance requires systematic observations and specific diagnostic criteria to ensure precision. An important part of surveillance is to determine who, when, and where: who is affected (e.g., age and other personal characteristics, contact with others who are ill), when the disorder occurs (e.g., year-to-year variations, season, temporal course of the outbreak), and where it occurs (e.g., geographic locations, urban or rural, local ecology). Second, an important task is to use surveillance and other data to develop an understanding of the epidemiology of the infection, which often provides clues to its etiology and pathogenesis and to approaches to controlling the disease. The third role of epidemiologists is that of monitoring the effects of various control measures, including assessment of the safety and efficacy of new vaccines, and their effects on microbial ecology. A description of how the efficacy of vaccines is determined is provided at the end of this chapter.

The increasing magnitude and speed of international travel enhance the likelihood of global spread of disease and complicate approaches to prevent or contain epidemic infections. Many of the emerging infections are not limited geographically by their ecologic requirements. The nations of the world increasingly depend on each other for surveillance, a task not easily accomplished given the logistics; costs (in the presence of other needs and priorities, particularly of many developing countries); and the required standardization, collaboration, communication, coordination, and centralized resource for assembly and analysis

of surveillance. In 2014–15, the outbreak of Ebola virus infections in Western Africa demonstrated all these issues of global spread. Although the WHO, the Pan American Health Organization, the U.S. Military and Public Health Service, and various other organizations maintain surveillance systems and laboratories in various parts of the world, these efforts at present are considered to be inadequate except for some infections and in some areas. The development of comprehensive national and worldwide surveillance systems has been urgently recommended.³⁶

BIOSTATISTICS

Statistical Significance

Stochastic statistics deals with probability. Most readers are familiar with the use of *P* values to assess the *statistical significance* of a finding from a study. Usually, the threshold used to separate "significant" from "nonsignificant" results is a probability (*P* value) of $<.05$, which means that (arbitrarily, by convention) if a result is likely to be observed by chance fewer than 1 in 20 times, the finding is considered to be statistically significant. It must be emphasized, however, that statistical significance and clinical significance are very different. A statistically significant result means that the result is considered unlikely to be attributable to chance alone. As we shall see, the *P* value is related not only to the magnitude of the difference between the things that are being compared (e.g., a characteristic of either the exposed and the unexposed groups in a longitudinal study or the cases and controls in a case-control study) but also to the size of the sample. Consequently, differences that are clinically unimportant (e.g., a difference in mean weight of 0.2 kg between two groups, a difference of 3% in the distribution of Caucasians between two groups) can be statistically significant if the size of the sample is large. Of importance is to remember that a statistically significant finding may be of no clinical significance.

By the same token, the "magic" *P* value of .05 itself may be misleading because it is an arbitrary threshold; in fact, there usually is little difference in the results associated with a *P* value of .04 and one associated with a *P* value of .06. If the size of a sample is small, a large, clinically important difference may not be statistically significant. One should not automatically dismiss the importance of a finding for which the *P* value is .05 or higher.

Hypothesis Testing

In most epidemiologic studies, stochastic tests are used to check the validity of a hypothesis. By convention, one tests the validity of the *null hypothesis* that there is no difference in either the mean value of the characteristic (for continuous variables) or the frequency distribution of the characteristic (for categorical values) between the groups being compared. In essence, one is testing the probability that the two samples being compared (exposed subjects versus unexposed subjects or cases versus controls) emerged from the same population—that is, whether a difference between the groups could have been the result of chance if the two samples were selected randomly from the same population or whether the difference is so great that it probably (<1 chance in 20, or $P < .05$) did not occur by chance; that is, the samples probably actually represent a true difference in the populations of either exposed subjects versus unexposed subjects or cases versus controls.

Hypotheses can be either *bidirectional* (*nondirectional*) or *unidirectional* (*directional*). A nondirectional hypothesis asks whether an association exists between exposed and unexposed subjects, but it does not assume in which direction the association will occur. For example, one might ask whether an association exists between the height of fever and the outcomes of children with typhoid fever without specifying whether the association would be in the direction of better or worse outcomes (perhaps high fever indicates a more severe infection, or perhaps it indicates a more vigorous immune response). In such instances, the associated *P* value should be interpreted in a bidirectional, or *two-tailed*, manner because the distribution of the test statistic contains two "tails," one at either end of the curve; the *P* value represents the sum of the area under the two tails of the curve. In effect, one is specifying that for a result to be statistically significant, the probability of the result being in a positive direction is less than 2.5% and the probability

of the result being in a negative direction is less than 2.5%. Most tables of P values provide results that are to be interpreted in a two-tailed manner (because this is the most conservative approach to testing a hypothesis), so the P value for a given test statistic can be read directly from the table.

In some instances, however, one might have good reason to suspect that an exposure is associated with an outcome in a unidirectional manner (e.g., that possession of a handgun is associated with an increased risk of sustaining a gunshot wound). If, in advance, the investigator decides to test this hypothesis in a unidirectional manner (the null hypothesis for which would be that ownership of a gun is not associated with an increased risk of incurring a gunshot wound), interpreting the results of a test statistic in a unidirectional, or *one-tailed*, manner might be appropriate. To derive a one-tailed P value, the two-tailed value is divided by 2. Thus, if the two-tailed P value is .06, the one-tailed value for the same result is .03. Clearly, obtaining statistically significant results by testing hypotheses in a unidirectional manner is easier. However it is important to specify before the study is conducted the *a priori* plan for how the results of statistical tests will be interpreted. Furthermore, although many hypotheses might seem to lend themselves to unidirectional analyses (e.g., one might think that an experimental vaccine that has been shown to be immunogenic could only be beneficial), in fact, unidirectional analyses are used only rarely. First, the possibility that an exposure may have an effect opposite to that expected usually cannot be ruled out in advance. For example, researchers found that persons who were immunized with a vaccine composed of inactivated respiratory syncytial virus had an increased risk of developing symptomatic infection with the virus. In addition, because two-tailed interpretation of data is more conservative, many authorities (e.g., editors of journals and such licensing agencies as the FDA) demand two-tailed analyses.

Type I Error, Type II Error, and Statistical Power

Two types of errors can be made when testing the validity of a null hypothesis. The first occurs when the null hypothesis is true but is rejected erroneously, which leads to an erroneous conclusion that a difference exists between the exposed and unexposed subjects; this kind of mistake is termed a *type I error*, or α error. If a test statistic with a P value of $\leq .05$ is accepted as statistically significant (and the null hypothesis is rejected on that basis), approximately 5% of the time a type I error is made because if no difference actually exists between the groups, that result still will occur by chance 1 in 20 times. By contrast, if the P value is $< .001$, a type I error will occur fewer than 1 in 1000 times if the null hypothesis is rejected.

The other kind of error, *type II error*, or β error, occurs when the null hypothesis erroneously is not rejected even though a difference between the two groups truly exists. If the P value associated with the result is .05 or greater, the probability that the null hypothesis is false is not sufficiently low to reject it (even though the probability that the observed result could have occurred by chance may be only .06).

Type I and type II errors are mutually exclusive. If one rejects the null hypothesis, one risks committing a type I error, the probability of which is equal to the P value. In such instances, a type II error cannot occur. If one accepts (i.e., fails to reject) the null hypothesis, one may commit a type II error (in which case a type I error cannot occur). The probability of committing a type II error is not related directly to the observed P value. Instead, one can estimate the probability of committing a type II error (β error) before the study begins on the basis of an assumed (clinically important) degree of association between the exposure and the outcome. Certain assumptions also must be made about the magnitude of the effect among the exposed subjects and the frequency of the outcome in the unexposed subjects. One is calculating a unidirectional probability that, by chance, the study will fail to detect an association equal to or greater than the magnitude that is specified for what is, in effect, an *alternative hypothesis* (i.e., that an association truly exists between the exposure and the outcome). The *statistical power* of a study (the unidirectional probability that the null hypothesis of no difference between groups will be rejected given a specified degree of type I error—usually $< 5\%$) is equal to $1 - \beta$.

In designing a study, adequate statistical power is critical to ensure that a true association between the exposure and the outcome is not

missed erroneously. The probability of a type II error depends on the size of the sample, the degree of variance within the sample, and the magnitude of the association that one wants to be able to detect: the smaller the sample, the larger the variance, and the smaller the magnitude of the association that one wants to detect, the larger the β error (type II error) and the lower the statistical power of the study to detect an association. Of these factors, the investigator usually has control over only the size of the sample (because in the population the variance generally is a relatively fixed attribute of the characteristic being measured, and the magnitude of association that is chosen usually is the minimal association that is clinically meaningful; for example, to design a study of an experimental vaccine so that it could detect as little as 30% efficacy would not make sense because such a product would not be approved in most instances unless the magnitude of its effect was much greater).

Exactly what constitutes adequate power is debatable. Because enrolling a large number of subjects in a study often is expensive and time consuming, frequently the power that a study is designed to have depends on both the financial resources and the time available to conduct the study. A statistical power of 80% often is chosen as a reasonable compromise between ensuring that the study has a sufficient number of subjects to answer the research hypothesis and the realities of logistic and financial exigencies. On the other hand, if a pharmaceutical company has invested many years and millions (or billions!) of dollars to develop a new drug or a new vaccine, it may demand that a pivotal clinical trial of the product have at least 90% power to detect a clinically meaningful effect in an attempt to ensure that the product will be approved if it is efficacious.

Multiple Comparisons

Another more subtle problem in interpreting results arises when more than one hypothesis is assessed in a single study. If multiple tests of statistical significance are performed in a study, the probability that by chance alone the P value associated with any one variable will be less than .05 is substantially greater than 5%. In fact, the probability that by chance at least one test will be associated with a P value $< .05$ is equal to $1 - (0.95)^k$, with k equal to the number of independent tests of statistical significance that are performed. Thus, if 10 different hypotheses are tested, a 40% probability exists that at least one of them will be statistically significant (i.e., that at least one of the tests will have a P value of $< .05$). Of course, this matter violates the arbitrary rule that we consider a finding to be statistically significant only if it is likely to have occurred by chance less than 5% of the time. If multiple different associations in a study have P values $< .05$, determining which occurred by chance and which truly are statistically significant is difficult.

On the other hand, studies often are expensive, time consuming, and logistically difficult to conduct. Therefore, sometimes a reasonable approach is to try to increase efficiency by assessing more than one hypothesis in a single study. To address this problem, one can specify in advance the *primary hypothesis* and the *secondary* and *tertiary hypotheses*. One then might give most credence to the statistical test of the primary hypothesis. Another approach is to raise the threshold used to define statistical significance by dividing .05 by the number of different tests that are performed. Thus if five independent hypotheses are tested, any one would have to be associated with a $P < .01$ before the null hypothesis would be rejected. However, this approach might be too stringent because the different hypotheses that are being tested often are not truly independent, and the probability that two or more associations will be statistically significant may be greater than the product of their individual probabilities. For example, one might assess whether infection is associated both with diarrhea and with vomiting; if it is associated with one of these symptoms, usually a higher than chance probability exists that it also is associated with the other. At the least, an investigator should acknowledge this potential problem and its consequences before drawing conclusions from the study.

Tests of Statistical Significance

Going into detail about the many different stochastic tests that are available is beyond the scope of this chapter. However, several general comments, as well as descriptions of a few commonly used tests, are in order.

Tests of statistical significance are either parametric or nonparametric. The test statistic of a *parametric* test is based on the assumption that the frequency distribution of the characteristic being assessed in the source population follows certain parameters. For example, for certain tests, one assumes that the characteristic in the population has a normal distribution. If the assumption is violated (e.g., the characteristic is not distributed normally), the statistical test will not be valid. In such instances, an appropriate approach might be to use a test based on a different, skewed distribution, such as the *Poisson distribution* for rare events, which might reflect more accurately the distribution of the characteristic in the population.

Alternative approaches to assess the statistical significance of differences between groups, if the distribution of the characteristic in the population is known to be highly skewed, include transforming the data so that they are normalized, usually by converting the values to their logarithmic equivalent, or using a *nonparametric* test.⁶⁶ Nonparametric tests, such as the Mann-Whitney *U* test and the Wilcoxon rank sum test, do not depend directly on the numerical values of the data; instead, the individual values are ranked in order of their values, and the statistical analyses are based on the relative ranks of the values in the different groups rather than on an assumed distribution in the population or in the sample.

For large samples, parametric tests usually are valid and often are easier to calculate than are nonparametric tests. For smaller samples and for samples with highly skewed distributions, nonparametric tests or tests that use log-transformed data may be preferable.

Continuous Variables

To test the statistical significance of differences between groups in continuous variables (e.g., degree of fever, intelligence quotient, age, or a score on a standardized questionnaire), the mean values of the different groups can be compared.⁶⁹ The tests of statistical significance use the magnitude of the difference of the means and the variance in the sample to assess the probability that the difference could occur by chance. If more than two groups are being compared for a single variable, the procedure is called *one-way analysis of variance*. The null hypothesis is that the mean values from each group are the same (i.e., that the different groups are random samples from the same population). The total variance in all the subjects is separated into the amount that is attributable to differences between the groups of subjects (the *intergroup variance*) and the amount that is attributable to differences among the subjects within each group (the *intragroup variance*). The greater the quotient of the intergroup variance divided by the intragroup variance (the *F ratio*), the more likely that differences between the groups are statistically significant (i.e., that they are not due to chance variation). The statistical significance of the *F* ratio can be determined from the *F test* table of *P* values. When this type of test is performed to assess the statistical significance of the simultaneous effects of two factors (by stratifying into additional groups), the test is called *two-way analysis of variance*.

The familiar *t test* is just a special form of one-way analysis of variance in which the means of just two groups are compared. A *one-sample t test* assesses whether the mean value of the study sample is statistically significantly different from the mean value in the source population. It assumes that the mean value in the source population is known and is calculated by dividing the difference of the mean of the sample minus the mean of the population by the quotient of the variance of the sample divided by the square root of the number in the sample.

A more common use of the *t test* is to assess the statistical significance of the difference between the mean values of either a characteristic or an outcome of subjects in two different samples (e.g., of the exposed and the unexposed groups in a study). The null hypothesis of this *two-sample t test* is that the mean values of the two samples are not statistically significantly different (i.e., that they could be random samples from the same population). The *t test* statistic is equal to the difference in the mean values of the two samples divided by the square root of the pooled variance of the samples (the standard error of the difference of the means of the two groups). The *P* value of the result (*t*) is read from the table of the *t* distribution, with the degrees of freedom equal to the sum of the number of subjects in each sample minus 2.

TABLE 6.4 2 × 2 Contingency Table

	Outcome Present	Outcome Absent	Total
Exposed	a	b	a + b
Unexposed	c	d	c + d
Total	a + c	b + d	N

$$\chi^2 = [(ad - bc)^2 N] \div [(a + b)(a + c)(b + d)(c + d)]$$

Categorical Values

The chi-square statistic (χ^2) commonly is used to assess the statistical significance of differences in categorical values between groups.⁶ Most often, proportions of two different groups (e.g., the proportions of the exposed and of the unexposed groups in which the outcome developed) are compared. Typically, the data are displayed in a 2 × 2 *contingency table* (Table 6.4). The null hypothesis is that no association exists between the exposure and the outcome (or whatever the rows and columns represent)—that is, that the two groups could be random samples from the same population. This hypothesis is tested statistically by comparing the number of subjects who would be expected to be in a given cell by chance with the actual frequency (the observed frequency). The expected frequency can be calculated from the total number of subjects in the rows and the columns (the marginal totals) and is equal to the product of the number of subjects in the row times the number of subjects in the column divided by the total number of subjects in the sample.

The value of χ^2 (with *N* equal to the total number of subjects) is shown in Table 6.4. The statistical significance of χ^2 can be determined by reading the *P* values from a table of the χ^2 distribution. The larger the value of χ^2 , the less likely that the observed proportions could have occurred by chance. Unfortunately, assuming that the probability that the observed proportions of a random sample of subjects will follow the χ^2 distribution is not necessarily accurate if the expected frequency of any cell is small. Consequently, many experts use a *continuity correction* (sometimes called the *Yates correction*) to adjust for the deviation from the smooth, continuous theoretic distribution of χ^2 when the discrete values of small numbers of expected subjects disrupt the validity of the assumed distribution. The equation for χ^2 with the continuity correction is

$$\chi_c^2 = [(ad - bc) - (N/2)]^2 N \div [(a + b)(a + c)(b + d)(c + d)]$$

If the expected frequency in any cell is very small (often defined as <5), the χ^2 test, even with the continuity correction, is not a valid estimate of the probability that the observed values could have occurred by chance. In such instances, the *Fisher exact test*, which is based on a hypergeometric distribution, should be used to assess the statistical significance of differences in categorical values.

Confidence Intervals

Although the validity of a null hypothesis typically is tested by stochastic tests and the use of *P* values, construction of a *confidence interval* (usually a 95% confidence interval [CI]) has the advantage of providing information about both the precision of the estimate of the association (the narrower the confidence interval, the more precise the estimate) and its statistical significance.⁸ CIs have become standard components of reports of the results of epidemiologic studies.

Analyses of studies are concerned with both estimation (of the “true” value of the association between the exposure and the outcome in the population) and hypothesis testing (i.e., what is the probability that any association observed could have occurred by chance alone). A sample of the population is enrolled in any study. The association observed in the study is hoped to be an accurate estimate of the true value of the association in the entire population. However if an unbiased study were repeated many times, by chance alone the results would vary (because of random sampling error). A CI is a range of values based on the estimate and the spread of the data from a single study, within which the true value of the association in the population is likely to lie with

a specified probability (i.e., 95% of the time for a 95% CI, 99% of the time for a 99% CI). CIs provide information about both the magnitude of associations (so that the clinical significance of the estimate can be assessed) and their statistical significance. If the CI is calculated for a single outcome and if the 95% CI for the difference between two groups does not include zero, the outcome is statistically significant (i.e., <5% probability that the null hypothesis of no difference existing between the groups is true). If the CI is for a risk ratio or an odds ratio, the association will be statistically significant if the 95% CI for the association does not include 1 (i.e., <5% probability that the null hypothesis that no association exists is true). CIs can be calculated with both continuous and categorical data, as well as for estimates of a single proportion and for differences (or associations) between two groups.

Adjustment for Potential Confounding Variables

The effect of confounding variables on the associations between exposure and outcome may be controlled in either the design or the analysis of a study. Random allocation of subjects to the exposed and unexposed groups is a common strategy to avoid the effect of confounding in longitudinal studies. Although randomization actually ensures only lack of bias if a confounding variable is distributed unevenly between the groups (because an uneven distribution is as likely to favor the exposed group as the unexposed group), randomization is likely to be effective in preventing confounding if the size of the sample is large (which renders substantial inequalities between groups in the distribution of an independent variable unlikely to occur). Nonetheless, an investigator must check to ensure that confounding does not occur, even in a randomized clinical trial.

Another way to ensure that a potential confounding variable does not affect the results of a study is to *match* on that variable. Subjects in the exposed and unexposed groups (or, in a case-control study, the cases and the controls) can be matched on certain variables that are known to be associated independently with both the exposure and the outcome. Such matching can be achieved either by matching subjects individually or by *frequency matching* (i.e., ensuring that the overall frequency distribution of the potential confounder is the same among the cases and the controls). Matching can ensure that the matched variable (e.g., race, age) does not affect the observed association between exposure and outcome.

One disadvantage of matching is that the effect of the matched variable on the association between exposure and outcome cannot be assessed as it might be if either stratification or multivariable analysis were used to control for confounding. If matching is used in the design of the study, analyzing the data with special tests for matched designs is necessary. For example, in a matched-pairs case-control study, only discordant pairs (matched pairs in which the cases and controls differ in their exposure status) provide information. Calculation of the matched odds ratio and the associated test of statistical significance (McNemar χ^2) is shown in Table 6.5.

Adjusting for the effect of potential confounders in the analyses also is possible. One way to accomplish this adjustment is with *stratification*, which is performed by dividing the data into different groups, or *strata*, according to the potential confounder. For example, a study may indicate that children whose parents both work were three times more likely to become febrile during the course of a study than were children whose parents both do not work. We may suspect, however, that it is not

having both parents at work, per se, that results in this increased risk of fever; rather, another factor probably is related independently to the risk of fever and to the probability that both parents work. Attendance at group daycare is such a factor. If we stratified the results of the study by whether the children attended group daycare, we most likely would find that a disproportionate number of children whose parents both work also attended group daycare. When the risk ratios in the two different strata are combined (by using the Mantel-Haenszel technique), we probably would find that the apparent association between having both parents work and the risk of fever disappears when the effect of attendance of group daycare is controlled by stratification.

Advantages of stratification are that it can be understood easily and it can be performed without changing the design of the study after it is completed. One disadvantage is that it requires being able to identify and to measure accurately the potential confounders (which is not necessary if one allocates subjects to different groups randomly). In addition, if several different potential confounders exist, performing the calculations may be difficult and time consuming, and the sizes of the individual strata may be so small that the ability to make statistical inferences is poor.

Finally, one can adjust for confounding with the use of one of many multivariable statistical techniques, such as *multiple linear regression* (if both the dependent and the independent variables are continuous) or *logistic regression* (if the dependent variable is dichotomous and the independent variables are either categorical or continuous). Providing a detailed description of multivariable techniques is beyond the scope of this chapter. However, in general, these techniques involve creating a mathematical model that fits the data and then using that model to analyze various associations.^{5,6,17,19,31,34,62} Although multivariable techniques are a powerful tool for both assessing the effects of and controlling for potential confounding variables, they depend on mathematical assumptions that may not always be valid and use techniques that are not intuitively obvious.

Meta-Analysis

The term *meta-analysis* refers to a number of different types of analyses. The common feature of all meta-analyses is that they summarize the results of two or more different studies. The term often is used to refer to a quantitative technique in which the results of different studies are combined after they are weighted in the calculations according to the sizes of their samples and the variances of their results. The term also sometimes refers to a qualitative analysis of a group of studies, including critical analyses that rate the methodologic soundness of different studies but do not combine their results quantitatively. For example, one might review a group of studies that reached different conclusions about a topic. If the methodologically rigorous studies had similar results that differed from those of the weaker studies, one might conclude that the results of the more rigorous studies were more likely to be valid.

The concept of producing a single, statistically valid result by combining the results of different, often contradictory, studies has great appeal. However, quantitative meta-analysis has many shortcomings. Perhaps chief among them is that no distinction is made between studies that are sound methodologically and those that are not. Thus, the results of a meta-analysis may be dominated by a study that is large but is methodologically questionable, whereas a superbly performed but smaller study may fail to override the impact of the larger study in the meta-analysis. Another major problem is the selection of studies to include in a meta-analysis. Should only published, peer-reviewed studies be included? Clearly a bias exists that studies with positive results are more likely to be published than studies with negative results. Imagine that many small studies with poor statistical power are conducted and submitted to journals for publication. If the study found no association with the putative risk factor, it likely would not be published on the grounds that the statistical power of the study is poor (i.e., the risk of making a type II error and erroneously concluding there is no association when such an association truly exists is great). On the other hand, if the study did find a statistically significant association with the risk factor, it might be published and could be included in a meta-analysis. If many such small studies that found an association were published, but even more small studies that did not find an association were not

TABLE 6.5 Analysis of a Matched Case-Control Study

Controls	CASES

published, this kind of *publication bias* could lead to erroneous conclusions in a meta-analysis. Should the analysis be limited to only those studies that meet certain basic criteria for methodologic rigor (and who should decide on the criteria and whether they are met), or should only randomized clinical trials be included? What formula should be used to weight the different studies? Is combining the results of methodologically different studies valid? Results of meta-analyses should be interpreted with great circumspection.⁷²

DIAGNOSTIC TESTS

Although clinicians typically order diagnostic tests many times each day, misinterpretation and misuse of diagnostic tests are extremely common occurrences.⁵⁶ The widespread practice of interpreting continuous values (e.g., the total white blood cell count) in a dichotomous manner (so that the result is either “normal” or “abnormal”) and failure to appreciate fully the difference between the accuracy of a diagnostic test (i.e., its sensitivity and specificity) and its predictive value are major factors in the misuse of diagnostic tests.

What Is Normal?

In most instances the cutoff for an abnormal test of a continuous variable, such as the total white blood cell count or the concentration of antibodies against an infectious agent, is based on the distribution of the results of the test in the population. One usually assumes that the distribution of most such results in the population will follow a Gaussian (or “normal”) distribution, which is illustrated by the bell-shaped curve in Fig. 6.1. Gauss and other statisticians used the term *normal* to refer to the shape of this curve. However, in medicine, the term *normal* long has been used to mean something very different—the dichotomy between a state of health (*normal*) and one of disease (*abnormal*). Unfortunately, the different meanings of these terms often have been used interchangeably, which has added to confusion in the interpretation of diagnostic tests.

In a normal distribution, the mode (the most frequent value) is the mean value, and 68.3%, 95.4%, and 99.7% of the values lie within (\pm) 1, 2, and 3 standard deviations (SD) from the mean value, respectively. The cutoff for an abnormal test result often is defined arbitrarily as any value that is more than 2 SD from the mean of a normally distributed

population; thus, 5% (actually 4.6%) of the population would be categorized as abnormal. Half the people with abnormal results will be 2 SD below the mean, and half will be 2 SD above the mean. Thus, 2.5% (actually 2.3%) of the population will have abnormally high values. In some instances, 3 SD (or some other arbitrary parameter) is used to determine the cutoff. However, it is important to realize that these definitions of normal and abnormal are merely statistical models that should not necessarily be translated to mean that 2.5% of the population is “diseased.” As noted earlier, with this kind of statistical logic, the diagnosis of disease may be related to the number of tests performed because if multiple tests are conducted, the likelihood that the result of any one will be abnormal is increased. If 15 independent tests are performed on a patient, the probability that any one of the test results will be abnormal by chance is 54%.

Other statistical models might be more appropriate for assessing a diagnostic test. For example, interpreting diagnostic tests would be relatively easy if two separate, nonoverlapping normal distributions of diseased and disease-free patients existed. Unfortunately, although this model may apply for some rare conditions (e.g., genetic disorders in which affected persons are missing an enzyme that metabolizes certain substances, which leads to uniquely high concentrations of the substance in persons with the disorder), the model rarely is applicable. A model that is more appropriate for most infectious illnesses is shown in Fig. 6.6. In this model (the example of which uses levels of serum calcium), the diseased and nondiseased populations have separate, partially overlapping distributions. The specificity of a diagnostic test is related directly to the degree to which the two distributions overlap.

Accuracy of a Diagnostic Test

Two important characteristics of a diagnostic test—its *reproducibility* and its *validity*—are the key components of its accuracy. The reproducibility (sometimes called *reliability* or *precision*) of a test simply is the degree to which retesting yields the same result. A test that provides results that are not reproducible is of little diagnostic value. The validity of the results of a diagnostic test may be divided into two components: *sensitivity* and *specificity* (Table 6.6). The *sensitivity* of a test is the proportion of persons with disease who are identified accurately by the test as having disease (true positives/[true positives + false negatives]). The *specificity* of a test is the proportion of persons without disease

FIG. 6.6 Overlap in values of randomly performed tests in a population in which most of the people are healthy (curve on the left) but some of the people are diseased (curve on the right). A person with a level of calcium below point A would be unlikely to have hyperparathyroidism. A person with a level of calcium above point B would be likely to have an abnormality in calcium metabolism, possibly hyperparathyroidism. A person with a level of calcium between point A and point B may or may not have an abnormality in calcium metabolism. (Note: The normal range of calcium depends on the method used in a specific laboratory. In some laboratories, the range is from 8.5 to 10.5 mg/dL. In others, as in this illustration, it is from 9 to 11 mg/dL.) (From Jekel JF, Elmore JG, Katz DL. *Epidemiology, biostatistics, and preventive medicine*. Philadelphia: WB Saunders; 1996:88.)

who are identified accurately by the test as not having disease (true negatives/[true negatives + false positives]). The *diagnostic accuracy* of a test is the proportion of all persons tested who are classified correctly by the test ([true positives + true negatives]/all persons tested). The ideal test has both a specificity and a sensitivity (and therefore a diagnostic accuracy) of 1. Of course, no diagnostic test is that accurate. Indeed, a tradeoff exists between sensitivity and specificity—the more sensitive a test is, the less specific it is, and vice versa.

Although the sensitivity and specificity of a given test often are considered to be absolute characteristics of a test, in fact, these characteristics do depend on the types of patients included in the studies in which the indices of the test were developed. Indeed, tests that appear to be both highly sensitive and highly specific in preliminary studies commonly prove to be much less so when used in actual clinical practice because the preliminary studies that establish a test's sensitivity and specificity frequently are affected by problems of spectrum and bias.⁵⁴ If the patients enrolled in studies used to assess the test (both those with disease and those without disease) have a relatively narrow spectrum of clinical manifestations, both the sensitivity and the specificity of a diagnostic test may appear to be better than they actually are. For example, if one were to assess the sensitivity of a differential heterophile antibody test to diagnose infection with Epstein-Barr virus (EBV), its sensitivity would appear to be far better if all the subjects infected with EBV were teenagers with severe pharyngitis (a high proportion of whom will have a positive heterophile test result) than if it included subjects with a broader spectrum of manifestations of EBV infection (e.g., toddlers with symptoms of an infection of the upper respiratory tract who are much less likely to have a positive heterophile test result when infected with EBV). Likewise, the specificity of a diagnostic test may appear to be better when only asymptomatic, healthy persons are used as non-diseased subjects instead of including patients with other illnesses that produce symptoms similar to those of the target illness. The effects of

spectrum of the illness on sensitivities and specificities of a diagnostic test also have been reported for dipstick urinalyses as a diagnostic test for urinary tract infections.³⁵

In addition, it is important to realize that the cutoffs for classifying results as either normal or abnormal usually are somewhat arbitrary and may depend on how the test is used as well as the nature of the disease that one is trying to detect. If a diagnostic test is being used to screen a population for a relatively mild disorder with a low prevalence, one would want to use a cutoff that results in high specificity to avoid having a large number of false-positive results, even at the expense of lower sensitivity. On the other hand, if the diagnostic test is for a serious disorder or is used not for screening but for diagnosis in a targeted population with at least a moderate prevalence of the disorder (e.g., a white blood cell count in cerebrospinal fluid to detect possible bacterial meningitis in febrile children), one might want to err on the side of overdiagnosis and therefore use a cutoff with a high sensitivity at the expense of lower specificity.

Predictive Value of a Diagnostic Test

Sensitivity and specificity are important characteristics of a diagnostic test, but to calculate them, one must know whether the patients do or do not have the disease; clearly, if a clinician already has this knowledge, the test does not need to be performed in the first place. From the perspective of a clinician who is caring for an individual patient, the key characteristic of a diagnostic test is its *predictive value* (see Table 6.6). That is, if a test result is positive, what is the probability that the patient has the disease (*positive predictive value*)? Conversely, if a test result is negative, what is the probability that a patient does not have the disease (*negative predictive value*)? However, unlike sensitivity and specificity, the predictive value of a test depends critically on the prevalence of the disease among the subjects who are tested.

This concern is illustrated by the examples in Table 6.7. In example *a*, the prevalence of the disease in the sample is 1% and the positive predictive value of a positive test result is only 8.8%. By contrast, as shown in examples *b* and *c*, when the prevalence of disease in the sample rises to 10% and 50%, respectively, the positive predictive value of a positive test result rises to 51.4% and 90.5%, respectively, even though the sensitivity and the specificity of the test are constant. By the same token, as the prevalence of disease in the sample that is tested rises, the predictive value of a negative test result falls, although the negative predictive value remains reasonably good until the prevalence of disease becomes high.

It is important for clinicians to be aware of these epidemiologic truths when ordering diagnostic tests for patients. Sometimes a physician orders tests to “rule out” the possibility that a patient’s symptoms are caused by a disease that, based on the patient’s history, physical examination, and previous laboratory test results, is unlikely to be the cause of the problem (i.e., the “prior probability” that the patient has the disease

TABLE 6.6 Statistical Indices of a Diagnostic Test		
Result of Test	Disease	No Disease
Positive	a	b
Negative	c	d
True positives: a	Sensitivity = $a/(a + c)$	
False positives: b	Specificity = $d/(b + d)$	
True negatives: d	Positive predictive value = $a/(a + b)$	
False negatives: c	Negative predictive value = $d/(c + d)$	

TABLE 6.7 Predictive Value of a Diagnostic Test With 95% Sensitivity and 90% Specificity With Different Prevalence of Disease in the Sample				
	Test	Disease	No Disease	Total
a*	Positive	95	990	1085
	Negative	5	8910	8915
	Total	100	9900	10,000
	Positive predictive value = 8.8%		Negative predictive value = 99.9%	
b†	Positive	950	900	1850
	Negative	50	8100	8150
	Total	1000	9000	10,000
	Positive predictive value = 51.4%		Negative predictive value = 99.4%	
c‡	Positive	4750	500	5250
	Negative	250	4500	4750
	Total	5000	5000	10,000
	Positive predictive value = 90.5%		Negative predictive value = 94.7%	

*Prevalence of disease: 1%.
†Prevalence of disease: 10%.
‡Prevalence of disease: 50%.

is low). Unless the specificity of such tests approaches 100% (which is unlikely for most serologic tests), in such situations the great majority of positive test results will be falsely positive; the physician then will be in the unfortunate position of ignoring the result, ordering additional diagnostic tests, or treating the patient for a disease that probably is not the cause of the symptoms.⁶¹ Consequently, clinicians should be selective in ordering diagnostic tests.

ASSESSMENT OF THE PROTECTIVE EFFICACY OF A VACCINE (OR OF ANY INTERVENTION)

Assessment of the protective efficacy of a vaccine is discussed in this section, but the same methods (with different outcomes specified, of course) can be applied to any intervention, such as a drug or physical therapy. The protective efficacy (PE) of a vaccine may be assessed with either experimental or observational studies. The classic way to assess a vaccine's efficacy is in an experimental, randomized, double-blind clinical trial. The major observational designs available are cohort studies and case-control studies—although a large variety of hybrid designs such as household exposure studies and indirect cohort studies are available—but complete descriptions of them are beyond the scope of this chapter.^{45,46} Table 6.8 illustrates calculation of the PE of a pneumococcal vaccine with data from clinical trials, cohort studies, and case-control studies.

Clinical Trials

In a randomized clinical trial, subjects at risk of acquiring the infection in question would be assigned randomly either to receive the vaccine (vaccinees) or not to receive the vaccine (controls). Subsequently, all subjects would be observed for occurrence of the infection during an appropriate period of follow-up. At the conclusion of the study, the *protective efficacy* of the vaccine, an index devised by Greenwood and Yule²⁶ to indicate the proportionate reduction in the frequency of disease attributable to the vaccine, would be calculated. PE is defined as follows:

$$\text{PE} = (\text{Risk of infection in controls} - \text{Risk of infection in vaccinees}) \div \text{Risk of infection in controls}$$

A PE of 100% indicates complete protection against infection, a PE of 0% indicates no protection, and negative values indicate that a greater risk of acquiring infection existed among vaccinees than among controls. By rearranging terms, PE equals 1 minus the risk of infection in vaccinees divided by the risk of infection in controls. Because the ratio in this equation is the relative risk of infection developing in vaccinees versus controls, $\text{PE} = 1 - \text{relative risk}$.

TABLE 6.8 Calculation of Protective Efficacy (PE) of Pneumococcal Vaccine

Clinical Trial or Cohort Study	Pneumococcal Infection	No Pneumococcal Infection	Total
Vaccinated	A	B	a + b
Not vaccinated	C	D	c + d
$\text{PE} = [(c/c + d) - (a/a + b)] \div (c/c + d) = 1 - [(a/a + b) \div (c/c + d)]^*$			
Case-Control Study	Pneumococcal Infection (Cases)	No Pneumococcal Infection (Controls)	
Vaccinated	A	b	
Not vaccinated	C	d	
$\text{PE} = 1 - [(ad) \div (bc)]^†$			

*The expression $[(a/a + b) \div (c/c + d)]$ is also known as the relative risk of infection in vaccinated versus unvaccinated persons.

†The expression $[(ad) \div (bc)]$ is the odds ratio relating vaccination to infection. In a case-control study, the odds ratio approximates the relative risk.

Observational Cohort Studies

In a cohort study, subjects at risk would be selected on the basis of whether they had been vaccinated or had been left unvaccinated during routine clinical care. The vaccinated and unvaccinated groups then would be monitored longitudinally to assess frequencies of infection. The analysis of a vaccine's PE for cohort studies is similar to that for clinical trials, but because the study is nonexperimental, the results are more subject to bias than are those of a well-conducted, randomized clinical trial.

Case-Control Studies

In a case-control study, patients with antecedent conditions that place them at high risk for pneumococcal infection would be eligible to be subjects. Patients with serious pneumococcal infection would become subjects in the case group. The control group would consist of subjects with similar high-risk conditions but without pneumococcal infection. The two groups then would be compared for the frequency of antecedent vaccination with pneumococcal vaccine.⁶⁴

In a case-control study, the strength of the relationship between vaccination and subsequent infection is measured by an odds ratio (the ratio of the odds of vaccination in the case subjects to the odds of vaccination in the controls). Because the odds ratio in a case-control study closely approximates the relative risk of pneumococcal infection in a longitudinal study and because PE is defined as 1 minus the relative risk, the value $(1 - \text{odds ratio})$ closely approximates the PE that would be calculated from a longitudinal study.

QUALITY IMPROVEMENT

There has been an upsurge of interest in efforts to improve the quality of care given to patients. Often interventions are developed that are thought to be beneficial and are very unlikely to produce harm. Consequently, they are implemented without rigorous testing (e.g., a randomized clinical trial) as would be required for either a new drug or new vaccine before it could be approved for use. Nonetheless, typically one would like to evaluate the effect of the new intervention, which might be a new policy or use of a new method to gather or disseminate information (e.g., use of an iPad). However, typically, there is no concurrent comparison group that can be used to assess the effect of implementation of the intervention, as would be done in an experimental study. Consequently, historical comparison groups usually are used. The problem is that one does not know what other changes occurred during the same period of time (or that may have begun even earlier) that might also affect the outcome that is being assessed. That is, is it valid to attribute changes over time in the frequency of the outcome to the intervention? While it is difficult to attribute a causal effect to an intervention in a nonexperimental study, techniques have been developed that provide more refined estimates of the true effect of the intervention—for example by adjusting for the trajectory of change in the frequency of the outcome that may already have begun before implementation of the intervention (e.g., an interrupted time series analysis). Extensive discussion of these methods is beyond the scope of this chapter, but there is an extensive literature on this topic.^{7,49,50}

The Common Cold

James D. Cherry

The common cold is an acute, communicable, viral disease characterized by nasal stuffiness, sneezing, coryza, throat irritation, and no or minimal fever. Although the terms *upper respiratory tract infection (URI)* and *nasopharyngitis* are used frequently as synonyms for the common cold by physicians and other health care workers, the practice should be discouraged; the term *URI* is too broad, and pharyngitis is not present in most colds. To add to the confusion regarding terminology, “a cold” frequently has an even more diffuse connotation to the layperson.

HISTORY

Although the common cold undoubtedly has had an impact on the events of history, the specific symptom complex in ancient times was overshadowed by more severe contagious problems (influenza, plague, smallpox) and by septic diseases (otitis, sinusitis, mastoiditis, pneumonia) that were complications of upper respiratory tract viral infections. The name *common cold* most certainly arose from the fact that the onset of symptoms included the feeling of chilliness on exposure to cold. This association was perceived as a cause-and-effect relationship. More than 200 years ago, Benjamin Franklin pointed out that colds were caught from other people rather than by exposure to cold.¹⁷⁸

In 1914, Kruse¹⁴⁰ showed that colds could be transmitted by the nasal instillation in healthy adults of Berkefeld-filtered nasal washings from ill individuals and that the causative agent was smaller than common bacteria. These findings were confirmed clearly in 1930 by Dochez and associates.⁶⁰ The way was paved for more extensive study of respiratory viral infections in 1933, when Smith and colleagues²⁰¹ reported the isolation and cultivation of an influenza A virus from a human.

The greatest contribution to the present understanding of the common cold has been the use of human volunteers under carefully controlled conditions. The Common Cold Research Unit at Salisbury, England, which was established in 1946,^{6,228} and volunteer studies at this institution and studies done in the United States* are responsible for much of the present understanding of colds in adults.

Although studies of respiratory illness in children also have been extensive, controlled virus challenge trials have not been done. Pediatric studies have been most useful in delineating the spectrum of clinical manifestations by age group and seasonal prevalence rates of the respiratory viruses.

During the past decade the use of molecular methods has increased our understanding of the contributions of both newly discovered and established viruses in the etiology of the common cold and other respiratory illnesses.^{77,152,193}

ETIOLOGIC AGENTS

Initial investigations into the etiology of the common cold were based on the hypothesis that only one etiologic agent needed to be discovered.⁶ Subsequent studies revealed that many different groups of viruses were involved etiologically and that many types frequently existed within each group. Table 7.1 lists the agents associated with colds. Each of these agents is covered more fully in other chapters; this chapter presents an overview. As a group, rhinoviruses are the most common cause of

colds in children and adults. Also of major importance in the etiology of colds are reinfections with parainfluenza viruses and respiratory syncytial virus (RSV). Although the quantitative contribution of coronaviruses to colds in children is less well known, they are significant contributors.^{61,77,88,186,193,210} More recent studies also indicate that human metapneumovirus and human bocavirus cause colds in children.*

Enteroviruses and adenoviruses have been implicated frequently in upper respiratory tract illnesses, but in most instances the illnesses do not conform to strictly defined colds. Reoviruses cause colds, but their contribution to the overall incidence is unknown. *Mycoplasma pneumoniae*, *Chlamydophila* (formerly *Chlamydia*) *pneumoniae*, *Streptococcus pneumoniae*, and *Haemophilus influenzae* infections were identified serologically in one study involving young adults with colds, but, in most instances, concomitant viral infections also were noted.¹⁵³ Other agents, such as *Coccidioides immitis*, *Histoplasma capsulatum*, *Bordetella pertussis*, *B. paraptussis*, *B. bronchiseptica*, *B. holmesii*, *Chlamydophila psittaci*, and *Coxiella burnetii*, also have been associated with illnesses with initial coldlike symptoms.

EPIDEMIOLOGY

The common cold is an exceedingly frequent illness in childhood. For rhinoviruses alone, more than 100 serologically different viral types can cause this illness. Nonetheless, a general predictability of incidence and seasonal occurrence exists for the common cold. In the past numerous epidemiologic studies were conducted on the occurrence of respiratory tract illnesses, but calculating a precise incidence of the common cold from these studies is difficult because criteria of disease classification were different. The findings in three carefully performed studies are presented in Table 7.2. Two of these studies were done approximately 60 years ago, and the other was done more than 40 years ago. These studies involved a wide range of family life settings, and the average number of colds per year in children varied from three to eight.^{11–14,26,84,153} Adults had on average approximately half the number of colds as their children.

In more recent times and in the era of the common use of daycare facilities, studies of the scope and magnitude of those presented in Table 7.2 have not been done. In one study published in the 1980s, the incidence of acute respiratory tract infections in daycare attendees peaked at 10 per child-year during the second 6 months of life.⁵⁵ A study by Wald and associates²³⁶ found that children in home care had 4.7 illnesses per year, whereas the illness rate was 7.1 per year in children in daycare. Of the illnesses, 89% in daycare attendees were respiratory tract infections.

In 2008, Grüber and associates⁹⁵ reported the history of respiratory infections in a cohort of German children. The children in this cohort were seen at ages 3, 6, 12, 18, and 24 months and then annually until age 12 years. The common cold illness rates per year were 3.1 in infancy, 3.2 at year 2, 2.1 at year 3, 2.3 at year 4, 1.8 at year 5, 1.3 at year 6, 1.1 at years 7 to 9, and 1.0 at years 10 to 12. The reason for these overall decreased rates in contrast to previous studies is not apparent, but less complete data ascertainment seems likely. In addition, smaller family size and less use of daycare could be factors.

In a study in Arizona, researchers found that 52% of 2-year-old children who attended large daycare centers had six to nine colds per

*References 1, 29, 47, 50, 55–58, 96–99, 102, 104–106, 121, 122, 129, 159, 162, 221, 222, 224, 226, 227.

*References 8, 9, 15, 43, 75–77, 109, 185, 193, 239, 240.

year.¹⁷ The conventional spread of colds has its initial focus in the school.^{11,14,26} School-aged children become infected and introduce secondary infections into the home. Under these conditions, the secondary attack rate was highest in other school-aged and preschool-aged children. Generally, the secondary attack rate in adult family members was approximately half that of the children. The introduction of infection into the family by adults is unusual. In crowded settings, such as a university, infection is common and can be associated with substantial morbidity. In a cohort study of more than 3000 college students, colds and influenza-like illness were common findings and were associated with missed classes, poor performance on class assignments, missed extracurricular activities, and increases in use of medical care.¹⁶⁷

As noted previously, the present trend toward the use of daycare centers and preschool programs has increased the number of primary infections in younger children and has made them the source from which secondary family infections frequently occur.¹⁶⁴ In a study that involved 606 children who received care at home or in a daycare program during the first 3 years of life, researchers found that children who attended a large daycare facility (six or more unrelated children) had more frequent colds at year 2 and less frequent colds at years 6 through 11 than did the children with home care only.¹⁷

In a national telephone survey in Australia in 2008–09 acute respiratory infections (ARI) were noted in 19.8% of families during the 4-week period prior to the telephone call.³⁹ Having a family member attending daycare was a significant risk factor for ARI in the family. In a daycare hand hygiene intervention study in the Netherlands, the yearly incidence of the common cold was 7.4 per child-year.²⁴⁸

Close personal contact between children is necessary for the transmission of viruses that cause colds. In the typical pediatric practice office setting, no increased risk for the acquisition of respiratory tract illnesses by well infants has been shown.¹⁵⁰ Among children, boys tend to have

more colds than do girls.^{11,26} In the conventional family setting, mothers tend to have at least one more cold per year than their spouses have.^{11,26,84,85} The usual incubation period of colds is 1 to 5 days.

In all nonisolated populations, colds occur more frequently during the winter months than during the summer.^{59,86,153,228} This seasonal discrepancy in incidence is as apparent in areas of high wintertime mean temperatures as it is in locations with extremely low temperatures. In the tropics, colds are more prevalent during the rainy season. Colds occur throughout the world. In isolated populations in which the number of people is few (e.g., members of Antarctic exploration teams and isolated island communities), colds do not occur unless introduced by a visiting person.¹¹⁵

Although colds can be produced regularly in volunteers, the method of transmission of viruses that results in colds under natural circumstances is unclear.* In individuals infected with respiratory viruses that cause colds, the greatest concentration of virus is in the nasal secretions. Children tend to have greater concentrations of virus than do adults, and they tend to shed virus for longer periods. Secretions related to coughing or saliva do not contain appreciable amounts of virus, and both are unlikely sources of contagion. During the process of talking, little virus is disseminated into the air. The greatest amount of virus from an infected individual is contributed to the surrounding environment by sneezing, nose blowing, and the general contamination of external surfaces (including the person's hands) with nasal secretions.

The route of acquisition of virus is by the nose and possibly the conjunctiva. With these facts in mind, one can easily see that a susceptible individual can become infected by inhalation of virus in droplet nuclei (small particles) resulting from a sneeze, by the direct nasal hit of virus containing large droplets from a sneeze, by nose blowing, or by the inoculation of virus (usually by the fingers of the recipient) from nasal secretions from disseminators that have been transmitted directly or indirectly. In children, most likely the spread either involves close contact with large droplets of nasal secretions containing virus that are applied to the nose from the hands of the future host or occurs by close-range airborne acquisition.

Considerable folklore is related to the catching of a cold. However, all available evidence to date indicates that cold weather per se, chilling, wet feet, and drafts neither cause nor increase the susceptibility of individuals to colds caused by viral infections.^{62,121} A study of 180 adult subjects showed that acute cooling of the feet was associated with the onset of common cold symptoms.¹²⁸ On day 4, after the cooling of the feet or the control procedure, significantly more subjects in the chilled group thought they were suffering from a cold (14.4%) compared with the control group (5.6%). The subjects who thought they were suffering from a cold had a history of more colds each year in contrast to subjects who did not develop cold symptoms. In this study, no virologic studies were done, so no evidence exists that the cold symptoms observed were caused by viral infections.

In a study of respiratory tract infections in Finnish military recruits, it was found that cold temperature and low humidity were associated with an increased occurrence of respiratory infections; a decrease in

temperature and humidity preceded the onset of the infections.¹⁵⁴ However no virologic data support the findings in this study.

In contrast, in controlled studies in which virologic studies were performed, no increased susceptibility to colds after exposure to chilling conditions was found.^{6,62,66} In adults, risk factors for increased susceptibility to colds include stress, smoking, high basal levels of catecholamines, infrequent exercise, low intake of vitamin C, low sleep efficiencies, and lack of diverse social networks.^{46,209} Physical stress, as opposed to mental stress, does not seem to be associated with increased susceptibility to colds. In a study of nine healthy men who were competitive cyclists who underwent intensive interval training, the men experienced enhanced performance but had no change in white blood cells, cytokine levels, or the frequency of upper respiratory tract infections.⁶⁷

A fascinating volunteer study in adults by Cohen and colleagues⁴⁵ was reported in 2008. In this study the subjects were given rhinovirus 39 or influenza A/Texas/36/91 intranasally. It was found that subjects with increased subjective socioeconomic status were less susceptible to upper respiratory tract infections than subjects with decreased subjective socioeconomic status. In contrast, no relationship was found between objective socioeconomic status and susceptibility to the two challenge viruses.

PATHOPHYSIOLOGY

The pathophysiology of human infections with viruses that cause colds is presented in the sections of this book covering the individual infectious agents. A general overview is presented here. Few studies on the pathophysiology of respiratory tract infections have been done in children; the material presented in this section has been derived mainly from studies in adults.* The clinical syndrome of the common cold can occur in association with more than 100 different viral types and in many instances can occur with either a primary infection or a reinfection with a particular viral type.

Although the primary site of virus inoculation in some colds may be on the conjunctival surface, most result from inhalation or self-inoculation of virus onto the nasal mucosa. After acquisition of a virus has occurred, infection of the cells of the local respiratory epithelium develops. This infection varies in the degree of cytopathology on the basis of the viral agent. The infection spreads locally, resulting in an increase in nasal secretions with an increased protein content. Symptoms (nasal stuffiness and throat irritation followed by sneezing) begin on the second or third day and are caused by cellular damage and irritation. Virus shedding is at its maximum in 2 to 7 days, although some shedding may continue for another 2 weeks.

Hilding¹¹⁴ examined biopsy specimens, scrapings, and smears of nasal secretions and noted that submucosal edema occurred initially, followed by shedding of the ciliated epithelial cells. By the fifth day, the epithelial damage had reached its maximum, with regeneration occurring during the next 10 days. Winther and associates²⁴³ performed similar studies and noted the sloughing of epithelial cells, but they found that the epithelial lining remained continuous with normal cell borders. On the second day of disease, an increase in the number of neutrophils in the epithelium and lamina propria occurred. Epithelial mast cells were not involved in the inflammation. The nasal discharge during the second to the seventh day is mucopurulent owing to its content of desquamated epithelial cells and polymorphonuclear leukocytes.

In experimental rhinovirus colds in adults, little or no discernible damage to the nasal epithelium has been shown.^{97,217,241,242} Arruda and associates¹⁰ noted in adults infected with rhinovirus types 14 and 39 that virus replicates in ciliated and nonciliated cells in the nasopharynx and that only a very small proportion of the cells were infected.

Because damage to the nasal epithelium is not noted in rhinovirus colds, apparently cell death is not the cause of symptoms. Naclerio and colleagues¹⁶³ and Proud and associates¹⁸⁷ found that kinins are generated locally, and their concentrations correlate with the severity of symptoms. The cause-and-effect relationship between kinins and symptoms is questionable, however, because treatment with a bradykinin antagonist failed to lessen symptoms.²²⁵ In addition, steroid therapy was found to

reduce the concentration of kinins in nasal wash fluid, but it did not affect clinical symptoms.

In 1994, researchers noted that interleukin-1 (IL-1) may contribute to the pathogenesis of rhinovirus infections.¹⁸⁷ Ongoing molecular and biochemical research has provided information on methods by which rhinoviruses interfere with the host response, induce epithelial expression of IL-6 and IL-8, and mediate infection via activation of kinases and receptor binding activity.^{69,135,160,177} In a human rhinovirus type 16 volunteer study it was found that IL-18 had a protective effect against colds and asthma exacerbations.¹²³ Conversely, it was noted that subjects with low nasal and bronchial IL-18 levels had increased respiratory symptoms. Similarly, research into the other viruses of the common cold has helped in the understanding of their similarities and differences, such as the cell-mediated immune response to human metapneumovirus and RSV.⁶⁵

In studies in children with acute upper respiratory tract infections, IL-1 β , IL-8, IL-6, and tumor necrosis factor (TNF)- α were found to be elevated markedly in nasal lavage fluid.¹⁶⁸ Pacifico and associates¹⁷² found that IL-8 concentrations and white blood cell and neutrophil counts were significantly greater in children with rhinovirus colds than in well children. In an adult volunteer study, Turner and colleagues²²⁷ noted a significant rank correlation between nasal obstruction severity, rhinorrhea severity, and nasal-wash albumin concentrations and the increase in IL-8 concentration from baseline to days 2 to 4 after virus challenge. In a study of 285 children with a parental history of asthma, other respiratory allergy, or both, blood specimens were obtained at birth and at 1 year of age.⁸⁹ The cytokine responses of mononuclear cells when incubated with phytohemagglutinin, RSV, and a rhinovirus were analyzed. Vigorous IL-13 and interferon (IFN)- γ responses to phytohemagglutinin and a marked secretion of IFN- γ in response to the viruses were associated with a reduced risk for developing wheezing with viral infections in the first year of life.

Pedersen and colleagues¹⁷⁶ studied nasal mucociliary transport in naturally acquired colds, noting that transport was reduced markedly during the acute illness and that slight impairment remained for approximately 1 month. They point out that because some children have four to six colds during a winter season, these children may have constantly impaired mucociliary transport.

Although viremia has been noted during infections with some of the viruses that cause colds, viremia is not known to occur during the typical common cold. The infection is restricted to the epithelial surfaces of the upper respiratory tract air passages, including the sinuses and eustachian tubes. With infection, local IFN is produced and presumably has a major role in controlling the infection.³⁸ Serum antibody and secretory antibody regularly result from infection. The roles of cell-mediated factors in immunity and disease pathogenesis of colds are unknown.

Levandowski and associates¹⁴⁵ noted in rhinovirus-challenged volunteers that total T cells, and particularly helper T cells, were depressed. The magnitude of this finding correlated with progression of infection and symptoms. In a study in which volunteers received rhinovirus type 39, Skoner and associates²⁰⁰ found a slight increase in helper (CD4⁺) and suppressor (CD8⁺) T cells during illness. Noting that asthma exacerbations and rhinovirus infections are associated with decreased pH and ammonium levels in exhaled breath condensates, Carraro and colleagues³³ studied whether a direct rhinovirus infection, the host immune response to the infection, or both decreased the airway epithelial cell surface pH in vitro. They found that airway epithelial cell pH is affected partly by T-helper type 1 cytokines. This decrease in pH can provide an innate host defense, inhibiting viral replication in the lower airways. By mechanisms not well understood, within already infected cells, low pH is thought to trigger uncoating of rhinoviral RNA from within the endosome, thus enabling viral replication.²⁵

The role of antibody (serum and secretory) in the protection against reinfection and clinical colds is complicated. High levels of secretory and serum antibodies seem to be protective against reinfections.* Clinically abortive colds probably are reinfection colds with early antibody recall. Fleet and colleagues⁸² demonstrated a short-lived heterologous

*References 10, 40, 63, 132, 168, 172, 188, 200, 217, 227, 228, 242, 247.

*References 36, 37, 82, 119, 120, 122, 124, 144, 203, 216.

resistance to rhinovirus colds that probably is not caused by interferon or antibody.

Unexplained constitutional factors also seem to control the clinical manifestations of colds.¹⁹⁴ Although studies have shown genetic disease susceptibility patterns related to tissue types, no studies relating to common respiratory tract infections have been done.⁴¹ In experimental coronavirus infections in adults, clinical severity correlated with detectable immunoglobulin (Ig)E in nasal secretions.³¹ This finding suggests that atopy may be related to symptoms in colds caused by coronaviruses. Although clinical symptoms and virologic data suggest that colds are upper respiratory tract diseases, some studies of pulmonary function also have indicated occult lower respiratory tract involvement.^{7,37,180}

In children younger than 5 years of age, primary traffic pollutants, ozone, and the organic carbon fraction of a particle size of less than 2.5 μm exacerbate upper respiratory infections.⁵²

CLINICAL PRESENTATION

Because the common cold is caused by more than 100 different viral types, considerable variation in the clinical manifestations occurs. As indicated in the beginning of this chapter, the limits of illness to be considered under the diagnosis of the common cold have been set arbitrarily but rigidly. A disappointing note is that although many comprehensive studies of respiratory viral illnesses of children have been done, little attention has been given to the details of upper respiratory tract infections.

Illness in children must be considered under two categories—infants and older children. The latter is similar to illness in adults. In studies involving 100 young adults, Jackson and colleagues¹¹⁹ noted that virtually all patients complained of nasal discharge, nasal obstruction, and sore throat; approximately 80% had malaise, postnasal discharge, headache, and cough; slightly fewer than 50% reported a feverish feeling and chilliness; and approximately 25% noted burning eyes and nasal membranes and muscle aching. In older children, the onset of illness is heralded by dryness and irritation in the nose and a scratchy feeling in the throat.¹⁶⁶ The initial symptoms are followed within a few hours by sneezing and watery nasal discharge; chilly feelings and occasionally muscular aches also are noted. Other complaints include headache, general malaise, anorexia, and low-grade fever.

After a variable period of 1 to 3 days, the illness changes; the nasal secretions become thicker and frequently develop a purulent appearance. Persistent nasal discharge, associated with the trauma of repeated blowing of the nose, leads to excoriation around the nose. Nasal obstruction leads to mouth breathing, which causes drying of the throat, increasing the discomfort in the throat. The usual duration of illness is approximately 7 days, but lingering cough and nasal discharge may persist for 2 weeks or more.⁶⁴

A recent review of reports relating to respiratory tract infections in children by M. Thompson and associates²¹⁴ noted that in children 50% of the colds resolved by day 10 and 90% by day 15.

In infants, the manifestations of illness may be more varied. The onset of illness in infants is associated more often with fever (38°C to 39°C [100.4°F to 102.2°F]) than it is in older children. Nasal manifestations in infants are similar to manifestations in older children, but the only other manifestations are irritability and restlessness. Occasionally, coryza is the only symptom. Nasal obstruction may interfere significantly with feeding and sleeping. Vomiting and diarrhea also may occur.

DIFFERENTIAL DIAGNOSIS

Because the clinical entity of the common cold is an arbitrary grouping of signs and symptoms limited to anatomic boundaries and is caused by many different viral types, the approach to the differential diagnosis must consider clinical and etiologic criteria. Many upper respiratory tract illnesses are caused by numerous infectious agents that should not be confused with colds. A diagnosis of the common cold should not be considered if objective pharyngitis, other enanthema, or evidence of obstructive airway disease is present. Because the common cold is an acute, self-limited disease, the diagnosis should not be considered in a

child who has persistent nasal signs or symptoms. Subacute or chronic illness should suggest the possibility of adenoiditis or sinusitis.

The most important differential diagnostic considerations are clinical entities of noninfectious etiology. Allergic rhinitis is a particularly important possibility in a child with “recurrent colds.” Careful attention to family history, a search for allergies, the presence or absence of nasal eosinophilia, and the serum IgE value help confirm or exclude this consideration.

Although not reported particularly in pediatric patients, mental stress can lead to vasomotor responses and rhinitis in some susceptible patients. Chemical irritants can cause coldlike symptoms; the clinical response varies greatly across individuals. Early symptoms of many illnesses, such as pertussis, croup, epiglottitis, measles, and diphtheria, are those of a cold, but in a short time, the more serious nature of the actual illness becomes apparent.

SPECIFIC DIAGNOSIS

The epidemiologic history is the most important aspect of specific diagnosis. In children, if exposure history is requested, a contact usually is uncovered. If strict attention to clinical criteria of the common cold has been adopted, routine laboratory study is unnecessary. Frequently, the physician has an urge to take a throat culture to rule out the possibility of group A streptococcal infection. Usually, this is unnecessary because nasal symptoms are not characteristic of acute streptococcal illness except in infancy, and pharyngitis is not within the limits of the diagnosis of the common cold. The white blood cell count also is of little use.

A specific diagnosis can be made by isolating virus from nasopharyngeal secretions. It is performed best by a nasal-wash technique¹⁰¹ or a nasopharyngeal swab or aspirate. With laboratory techniques (culture or polymerase chain reaction [PCR]) of diagnostic virologic facilities in university hospitals, public health laboratories, and in reference laboratories, all known common cold viruses can be identified.^{15,61,75,76,88,109,152,193,210} (See Chapter 253.)

TREATMENT

Although literally hundreds of over-the-counter (OTC) cold remedies are available, few offer benefit to the pediatric patient, and many may be harmful.* No clinically available antiviral agents have been shown effective in the treatment of colds.

In the approach to a child with a cold, the best assumption is that no therapy is indicated in most cases. On occasion, specific symptomatic care can be added in the individual case when it appears to be needed. Many children and adults feel miserable when they have a cold, and therapy with an analgesic often is used. Because aspirin is a risk factor for Reye syndrome in children, the use of acetaminophen rather than aspirin is prudent. The dose per single administration of acetaminophen by year of age is as follows: younger than 1 year, 60 mg; 1 to 3 years, 60 to 120 mg; 3 to 6 years, 120 mg; 6 to 12 years, 150 to 300 mg; older than 12 years, 325 to 650 mg. Administration may be repeated every 6 to 8 hours in young children and every 4 hours in older children. Acetaminophen rarely should be given to infants younger than 6 months of age.

In adult volunteers with rhinovirus infections, acetaminophen was found to be associated with suppression of the serum neutralizing antibody response, and an increase in nasal symptoms was noted, in contrast to subjects who received a placebo.⁹³ In another adult volunteer study, administration of naproxen resulted in a reduction in headache, malaise, myalgia, and cough in contrast to placebo.²⁰⁷ Choi and colleagues⁴² looked at five studies to compare the efficacy and safety of nonsteroidal antiinflammatory drugs (NSAIDs) versus acetaminophen in symptom relief for the common cold. They found no difference in effectiveness between NSAIDs and acetaminophen in common cold symptom relief.

OTC cough and cold medications that contain antihistamines, antitussives, expectorants, decongestants, and antipyretics/analgesics in various

*References 4, 8, 16, 19, 21, 23, 24, 28, 35, 34, 53, 56, 68, 70, 71, 87, 90, 91, 100, 111, 116, 118, 131, 138, 141, 147, 149, 155-157, 169, 171, 173, 175, 179, 182, 184, 191, 197-199, 202, 204, 208, 212, 219, 231-233, 235, 236, 246.

combinations are readily available for children.¹⁷³ Results of the Slone Survey noted that in a 1-week period, 10.1% of children in the United States received an OTC cough/cold medication.²³² Adverse events and deaths in children younger than 6 years have been observed.^{53,141,173,191,197,204,232,233} In 2007, a U.S. Food and Drug Administration (FDA) advisory group recommended that OTC cough and cold medications not be used in children younger than 2 years. Unfortunately, a large number of parents and other caregivers are not aware of the FDA recommendations on OTC cough and cold medications.^{156,231,245} The American Academy of Pediatrics in 2008 recommended that OTC cough and cold medications should not be used in children younger than 6 years.

Relief of nasal obstruction is the most important therapeutic consideration in young children. Locally applied or orally administered systemically active decongestants are used frequently, but neither their true efficacy nor their adverse effects have been evaluated carefully. Excessive use of sprays and drops with vasoconstrictive drugs can lead to rebound obstruction, which prolongs the illness. The associated drying effect of vasoconstrictive drugs administered orally can be expected to be deleterious to normal mechanisms of clearance. In young infants, sympathomimetic-antihistamine mixtures in oral drop dosage forms particularly are dangerous because respiratory depression may occur.⁹¹ In addition, in a controlled trial, brompheniramine maleate-phenylpropanolamine hydrochloride was found to be no better than a placebo in relieving cold symptoms in children 6 months to 5 years of age.⁴⁴ If vasoactive drugs are used, their use should be restricted to times when maximum benefit would occur (i.e., bedtime), and they should be discontinued within 3 days.

The use of isotonic saline drops and gentle aspiration may be effective in the temporary relief of nasal obstruction in an infant. However, a Cochrane Collaboration review noted that available data were not sufficient to demonstrate efficacy of saline nasal irrigation.¹³¹ It also noted that 40% of babies did not tolerate nasal saline drops. The general humidification of room air may be useful because this moisture tends to dilute tenacious nasal mucus and facilitate its elimination. In a Cochrane Collaboration review, steam inhalation was not shown to offer any consistent benefits in the treatment of the common cold.¹⁹⁸

Antibiotics have no place in the routine therapy of common colds.^{92,117,126,133,137,142,146,170,192,205} In children, persistent cough occasionally is a problem of such magnitude that it disturbs sleep. For cough, codeine and dextromethorphan often are used.²²⁹ No well-controlled studies support either the efficacy or the safety of codeine or dextromethorphan as an antitussive in children, however. Eccles⁷² suggested that the apparent efficacy of liquid cough syrups may be due to the sweetness of the products rather than their active ingredients. The proposed mechanism is that a sweet taste may affect cough at the level of the nucleus tractus solitarius by stimulating the production of endogenous opioids.

In the past, antihistamines were often given to children with colds, but efficacy had not been demonstrated.²³⁸ In more recent years, first-generation antihistamines, but not second-generation products, have been shown to lessen rhinorrhea in adults with colds.^{161,162,217,218,225} Doxylamine succinate, clemastine fumarate, chlorpheniramine maleate, and brompheniramine have been shown to offer benefit in controlled trials. The effect of these antihistamines is due to their anticholinergic properties. To date, no studies in children have been reported.

A major controversy relates to the efficacy of vitamin C in the common cold prophylactically and therapeutically. In two carefully controlled volunteer studies, the administration of 3 g of ascorbic acid per day did not prevent or alter the symptoms of experimental colds.^{195,237} In addition, several large controlled trials in which vitamin C and placebo preparations were used to prevent and to treat colds were conducted.^{5,32,48,49,73,112,129,181} Benefit was reported in some of these studies, whereas in others, no efficacy was noted. The reported benefits probably are a result of statistical artifacts and placebo effect owing to poor study design, rather than specific pharmacologic drug effects. The antihistaminic action of vitamin C^{230,249} probably afforded relief to some patients with allergic rhinitis who thought that their illnesses were colds. Because of the many toxic effects of ascorbic acid,¹⁸ and because its use in treating respiratory illnesses is questionable at best, giving children vitamin C in excess of normal daily requirements seems unwarranted.

For many years, efforts have been made to develop effective rhinovirus chemotherapy, but showing convincing efficacy in natural infection has been a challenge.¹⁷⁴ IFN alfa-2b administered intranasally has been shown to have some efficacy in the prevention of rhinovirus colds in controlled clinical trials.²⁰⁶ The effect is variable, however, and adverse effects of the medication are frequent occurrences.²¹¹ Intranasal IFN alfa-2b was ineffective in the treatment of naturally occurring colds but showed some benefit in experimental coronavirus colds.^{107,222} Studies in adults using an antiviral antiinflammatory combination for treatment of the common cold showed some benefit in contrast to either agent used alone.¹⁰⁰ However, the irritation caused by intranasal IFN alfa-2b and the drowsiness associated with first-generation antihistamines render these drug combinations suboptimal.

Zinc lozenges have been used to treat the common cold; the Internet and lay literature are full of claims of efficacy, although in well-done, controlled studies, efficacy has not been shown.^{70,71,79,125,151,183,221,236} However, a recent Cochrane Collaboration review noted that zinc administered within 24 hours of onset of symptoms reduced the duration and severity of the common cold in healthy people.¹⁹⁹ It also noted that prophylactic use reduced the incidence of colds and decreased school absenteeism and antibiotic use in children. The use of intranasal zinc preparations also is not well validated and raises some concern because of the possible development of the zinc-induced anosmia syndrome.^{4,23} In a double-blind, placebo-controlled trial, the use of intranasal corticosteroid (fluticasone propionate) offered no clinical benefit in young adults with colds and induced prolonged shedding of rhinovirus.¹⁸⁹

In a controlled trial in adults, a soluble intercellular adhesion molecule-1 product (tremacamra) reduced the severity of rhinovirus colds.²²⁶ The antiviral pleconaril induced an early reduction in severity of symptoms in adults with colds caused by rhinovirus.¹⁰⁸ Pleconaril is an antipicornavirus drug that interacts directly with viral capsid proteins. It blocks attachment of virus to cells through intercellular adhesion molecule-1 and subsequent uncoating and release of viral RNA.

In another randomized, double-blind, placebo-controlled trial, the symptomatic efficacy of pleconaril was linked to its *in vivo* antiviral effects and to the drug susceptibility of the infecting virus.¹⁷⁸ In March 2002, the Antiviral Drugs Advisory Committee of the FDA voted against recommending pleconaril for approval of its use in the treatment of the common cold in adults. This decision was based on drug interactions, poor risk-to-benefit ratio, and concerns of development of resistant virus.¹⁷⁴

Clarithromycin, a macrolide antibiotic, enhances mucosal immunity in mice by increasing levels of IL-12, IgA, and IgG.¹³⁴ In a controlled trial, however, clarithromycin had no effect on the severity of cold symptoms. The intranasal administration of nedocromil sodium has been observed to have a beneficial effect on rhinoviral infections in adult volunteers.²⁰ Mucolytics have emerged as potential therapeutics for modulating the function of airway epithelial cells and altering the course of viral infections.^{9,246} Leukoprotease inhibitors and pulmonary surfactant have been shown to be upregulated by ambroxol, a mucolytic and antioxidant agent.^{8,169}

In one study, adults who took sauna baths once or twice per week were found to have fewer colds than did members of a non-sauna-bathing control group.⁷⁴ In two studies, volunteers with colds did not benefit from inhaling heated vapor.^{83,171}

The list of available and proposed complementary and alternative medicines thought to be useful for prevention and treatment of the common cold is long.* Most studies evaluating complementary and alternative medicines have been carried out in adults, not children. Compounds that have been studied include *Echinacea*, immune stimulants, ipratropium bromide, pine bark extracts, probiotics, derivatives from red seaweed, vitamin D, Baker's yeast β -glucan, cranberry polyphenols, *Pelargonium sidoides*, and bovine lactoferrin/whey protein. Blinding subjects in placebo-controlled trials can be difficult, and the placebo effect seems to play a significant role in the popularity of all complementary and alternative medicines.^{21,24,34,56,111,219} Fluid extracts of *Echinacea* spp. are popular for the prevention and treatment of colds.^{19,94,130,217,224} Because several species of *Echinacea* have been used in prevention and treatment

*References 2, 3, 19, 22, 24, 28, 54, 68, 78, 81, 103, 136, 139, 148, 149, 158, 165, 215, 234, 235, 244.

studies, criticism of the negative results in some studies has been expressed by *Echinacea* advocates.^{24,35,90,138,196,208,212,219}

In a controlled trial, Taylor and associates²¹³ evaluated *Echinacea* for the treatment of upper respiratory tract infections in children aged 2 to 11 years. No benefit was noted, and the *Echinacea*-treated children had an increased occurrence of rash. Preparations of North American ginseng have been reported to decrease the frequency of colds in adults.^{16,157,184} In a study of North American ginseng extract involving children 3 to 12 years of age, no treatment benefit was noted.²³⁵

In a 2010 study in children 2 to 11 years of age, Paul and associates¹⁷⁵ found that the application of Vicks VapoRub to the child's neck and chest at bedtime gave symptomatic relief from nocturnal cough, congestion, and sleep difficulty caused by an upper respiratory tract infection. This was a controlled study that compared the children treated with Vicks VapoRub with those who had received petrolatum to the chest and those who had no treatment.

PROGNOSIS

The prognosis of common colds in children is excellent. Secondary complications do occur, however, and frequently require careful and prolonged therapy. The most common complications are otitis media, sinusitis, bacterial adenoiditis, bacterial pharyngitis, and lower respiratory tract bacterial infections. The primary viral pathogens identified in hospitalized children with lower respiratory tract infections include RSV, influenza A and B viruses, human metapneumovirus, parainfluenza viruses, adenoviruses, rhinoviruses, and enteroviruses.¹³⁷ Infections with multiple agents also occur.

PREVENTION

Studies in isolated populations have shown that when a particular respiratory viral infection has run through the entire group, no further respiratory viral illnesses can occur until a new infected individual enters the population. This type of evidence indicates that quarantine or isolation practices could prevent colds. However, today's average urban society is so complex that prevention through isolation procedures is impractical. Efforts to control the spread of respiratory virus should be minimal and practical. For children with undue susceptibility to complications, contact with crowds or infected children and adults should be avoided.

Probiotics are considered by many to be useful for the prevention of upper respiratory infections.^{2,54,103,136} In 2015, Hao and colleagues authored a Cochrane Database Systemic Review.¹⁰³ They felt that the overall data were poor but indicated that probiotics were better than placebo in preventing upper respiratory tract infections. They also felt that their use shortened illness duration, decreased school absence, and decreased antibiotic use.

In a double-blind, placebo-controlled study over a 6-month period in children 3 to 5 years of age it was found that the children receiving a probiotic twice daily had a decreased incidence of fever, coughing, and rhinorrhea with cold and influenza-like symptoms than did placebo recipients.¹⁴⁷ The children who received the probiotic had a significant reduction in days absent from group childcare and a reduced incidence of antibiotic use than did the placebo recipients.

The use of virucidal nasal tissues has been shown to reduce markedly the spread of rhinovirus colds in human volunteers and to reduce modestly colds in the family setting.^{57,80} Heikkinen and associates¹¹⁰ found that intranasal administration of an immunoglobulin preparation by nasal sprays twice per day significantly reduced the occurrence of rhinitis in children attending daycare centers. If confirmed, this form of prophylaxis might be useful for selected children. A study showed that organic acids commonly used in OTC skin care and cosmetic products had substantial virucidal activity against rhinoviruses. The amount of acid applied to the hands correlated directly with the prevention of infection in the deliberate infection model.^{220,223}

Although most infections of the oral cavity in children are odontogenic and may be treated simply with local measures, the occasional spread of these infections to adjacent or distant fascial spaces or to the maxilla and mandible may result in life-threatening complications. Consequently, careful attention, including liberal use of the dental consultation, should be given to such infections.^{32,78}

MICROBIOLOGIC CONSIDERATIONS IN DENTAL INFECTIONS

Normal Flora

That the oral cavity provides an environment favorable to the growth of microorganisms is substantiated by reports of bacterial counts of 10^8 to 10^{11} organisms/mL of saliva.^{8,13} More than 30 species of bacteria normally can be identified in saliva in varying proportions depending on a dynamic interaction of microbial ecosystems, including the tongue, the gingival crevice, and the presence of plaque.^{71,86} Age, anatomic relationships, eruption of teeth, presence of decayed teeth, diet, oral hygiene, antibiotic therapy, systemic disease, cancer chemotherapy,⁷³ and hospitalization can modify the microbial population. In the older literature, emphasis was placed on the role of *Streptococcus* and *Staphylococcus* spp. in producing odontogenic infections, to the exclusion of most anaerobic bacteria. This emphasis probably was the result of failure to culture satisfactorily for anaerobic organisms, and it is now well known that the ratio of anaerobic to aerobic organisms ranges from 3:1 to 10:1.^{8,19}

The nomenclature of the oral flora is changing rapidly as a result of the improved understanding of the genetic makeup of these bacteria provided by molecular biology techniques. Table 8.1 summarizes changes in nomenclature among selected members of the oral flora.^{20,93,92} Molecular methods based on polymerase chain reaction allow direct identification of bacterial species to be made from the oral flora and odontogenic infections by isolation of their DNA, RNA, or both. These methods have led to appreciation of the true oral flora, for which 60% of species are unculturable. In recent years, many new species and phylotypes have been identified in the normal and pathologic oral flora.

The flora of children is similar to that of adults, with several exceptions. At birth, the oral cavity is sterile, but colonization with *Streptococcus salivarius* occurs rapidly. This organism has been found in 80% of cultures taken from 1-day-old infants.⁹⁵ The percentage of *Streptococcus* spp. decreases from 98% at day 1 to 70% at 4 months⁶⁸ as other organisms become established. *Staphylococcus*, *Neisseria*, *Veillonella*, *Actinomyces*, *Nocardia*, *Fusobacterium*, *Bacteroides*, *Corynebacterium*, and *Candida* spp. and a variety of coliforms gradually become established by the time the child reaches 1 year of age. As the deciduous dentition erupts, anaerobic organisms become well established in the gingival crevice, yet the spirochetes *Bacteroides* and *Prevotella* spp. and related oral anaerobes, which commonly are associated with the gingival crevice in adults, seem to be present in fewer numbers in patients younger than 13 to 16 years.^{13,95} Eruption of deciduous teeth also is associated with the establishment of *Streptococcus mutans* and *S. sanguinis*, which adhere to the enamel surface.

Pathogenic Organisms

Not all residents of the oral flora are pathogens. In the odontogenic infections caries and periodontal disease, a progression from initiating infections caused by oral streptococci toward a predominance of oral anaerobes in the more severe and long-standing infections apparently occurs. Caries is initiated primarily by *Streptococcus mutans*, a member

of the α -hemolytic *S. viridans* group. As tooth decay progresses toward the dental pulp, *Lactobacillus* and *Actinomyces* spp. join the carious milieu. Severe pulpal infections generally are caused by a combination of these same oral facultative streptococci plus obligate anaerobes such as *Porphyromonas endodontalis*, formerly classified as *Bacteroides endodontalis*.⁹⁸

Periodontal infections also are polymicrobial; gram-positive aerobes, primarily streptococci, predominate in gingivitis, and the gram-negative anaerobic rods predominate in bone-destroying periodontitis. Juvenile periodontitis (formerly called *periodontosis*), a particularly aggressive periodontal infection in children and adolescents, shows a predominance of *Aggregatibacter actinomycetemcomitans* (formerly known as *Actinobacillus actinomycetemcomitans*) in its cultivable flora.

Orofacial odontogenic infections that spread beyond the teeth and alveolar processes are polymicrobial, yielding on average four to six isolates per case.^{12,53,66} With the use of molecular methods, even greater numbers of species can be identified in these infections, ranging from five to 18 species per case.²⁹ Severe orofacial infections have been associated statistically with *Fusobacterium nucleatum*.⁴¹ The concept of the progression from aerobic streptococci to anaerobic gram-negative rods in orofacial infections is supported further by studies that have found a predominance of streptococci in early infections (in the first 3 days of symptoms) and a predominance of anaerobes in late infections.⁵³ Table 8.2 lists the frequency with which the major pathogens in orofacial infections were isolated in two studies.^{42,57,89} Although the majority of bacterial identification studies are done with adult subjects, research indicates that odontogenic infections in children are caused by similar bacteria. In a recent study, *S. viridans* and *Neisseria* and *Eikenella* spp. were the most frequently isolated aerobic and facultative organisms. *Prevotella* and *Peptostreptococcus* spp. predominated among anaerobes.⁸⁸

Infections originating from nonodontogenic causes (facial trauma, surgical manipulation, tonsillitis) are included in most studies of soft tissue and fascial space infections, and contamination from the skin or oropharynx might allow aerobic organisms, such as *Staphylococcus aureus* and aerobic *Streptococcus* spp., to become established.¹³ In contrast, infections originating solely from the dental periapical tissues are much more likely to be predominantly anaerobic.

A pitfall in the identification of organisms as described in the older literature was the failure to culture satisfactorily for anaerobic organisms. The more current literature recognizes this fact.^{58,70} The preponderance of anaerobic organisms in odontogenic infections mandates the use of anaerobic and aerobic culturing techniques in situations in which cultures are indicated.

ANATOMIC CONSIDERATIONS

Most severe orofacial infections develop consequent to dental infection—periapical, periodontal, or pericoronal. Spread occurs along anatomic pathways of least resistance.^{8,19,45,56,97} Periodontal and pericoronal infections rarely have major sequelae because they generally drain from the gingival sulcus along the surface of the tooth into the oral cavity. Infections associated with the root apices generally are confined within the bony alveolar process (Fig. 8.1). Should spontaneous intraoral drainage occur through either the periodontium or the pulp chamber, further spread through the marrow spaces is unlikely. If such drainage does not occur, spread through bone (osteomyelitis) or perforation of the cortical plate of the affected jaw may occur. Infections associated with root apices close to the buccal cortical plate generally spread buccally, whereas infections close to the lingual or palatal cortical plate or maxillary

^aThis organism was not reported in this study.

sinus spread in those directions (Fig. 8.2). When penetration of the cortical plate occurs, infection involves the adjacent soft tissues and may manifest as cellulitis or a soft tissue abscess, which eventually may perforate the mucous membrane or skin as a sinus tract (Fig. 8.3).

Perforation of periapical infections through bone follows a typical pattern that results from the position of the root apices in relation to the bony cortex and to muscle attachments (Fig. 8.4). Infections involving maxillary anterior teeth and buccal roots of maxillary posterior teeth generally perforate labially or buccally, whereas infections involving palatal roots of posterior teeth perforate palatally or rarely into the maxillary sinus. The presence of the buccinator muscle attachment superior to the root apices usually confines these infections and fistulas to the oral cavity. In children, maxillary root apices often are superior to the buccinator, however, and infections may spread to the buccal or

FIG. 8.1 Radiolucency representing a chronic periapical abscess involving the mesial root of the deciduous second molar and the distal root of the deciduous first molar. The developing mandibular bicuspsids are seen inferior to the deciduous roots. The cause of the abscess is the deep carious lesions in both teeth, which appear to have penetrated the pulp chambers.

FIG. 8.5 Submental space abscess.

infraorbital space or to the periorbital tissues. They eventually may drain through the skin.

Infections of the mandibular incisor or canine tooth may spread either labially or lingually because the alveolar process is thin in this area. Labial perforation, which occurs more commonly, may be confined intraorally if the root apices are superior to the origin of the mentalis muscle but may spread extraorally if the apices are inferior to the mentalis

attachment (Fig. 8.5). Infections of the mandibular premolar and first molar often perforate buccally, whereas the second and third molars perforate lingually.

When spread of mandibular infections occurs medially, the relationship of the tooth apices to the mylohyoid muscle origin is significant

FIG. 8.6 Relation of tooth apices to the origin of mylohyoid muscle. (From Waite D. *Textbook of practical oral surgery*. Philadelphia: Lea & Febiger; 1978.)

(Fig. 8.6). From the first molar forward, the dental root apices are superior to the mylohyoid, and these infections localize intraorally in the floor of the mouth (sublingual space). The apices of the second and third molars generally are inferior to the mylohyoid and so the submandibular space is involved, with an extraoral presentation. As in maxillary infections, the relationship of the buccinator muscle to the root apices determines whether the infection spreads intraorally or extraorally.

Two fascial spaces commonly associated with odontogenic infections are the submandibular and masticator spaces.^{36,37,56} The submandibular space is formed within the superficial layer of deep cervical fascia inferior to the mylohyoid muscle and inferomedial to the mandible. Anteriorly and posteriorly, it is limited by the bellies of the digastric muscle. Within this space lies the submandibular gland and portions of the facial artery and anterior facial vein. This space is closely approximated to the sublingual and masticator spaces. Infections of the submandibular space may originate in these adjacent spaces and in the mandibular posterior teeth.

The masticator space also is formed within the superficial layer of deep cervical fascia. Its name is appropriate because its contents include the masseter, internal and external pterygoid, and temporalis muscles, as well as the mandibular ramus and the inferior alveolar neurovascular bundle. The submandibular, lateral pharyngeal, and retropharyngeal spaces are adjacent. Infections of the masticator space may originate in adjacent spaces or spread to it from periapical or pericoronal infections of the mandibular second and third molars and maxillary third molar.

TREATMENT OF ODONTOGENIC INFECTIONS

Patients with odontogenic infections may present with symptoms ranging from minor to life-threatening. Too often, a patient may be given a thorough systemic and extraoral head and neck evaluation while the intraoral search for the etiologic agent is overlooked.

A thorough oral examination begins with an evaluation of the degree of mandibular opening. Interincisal distance on wide opening extends 40 mm or more, even in young children. Painful limitation of the oral opening, or trismus, is associated with inflammation of the muscles of mastication and indicates spread of the infection to the masticator space. In association with a high fever, it can represent a serious turn of events. Teeth are inspected visually for caries, by percussion for tenderness, and by electric sensitivity or hot and cold stimulation for the pulpal pain response. Gingival tissues are probed for periodontal defects, and salivary glands are palpated for tenderness and milked to observe for purulent discharge from the duct orifices.

General Therapeutic Principles

As with infections elsewhere in the body, the principles of treatment of oral infections involve surgical drainage and antibiotics. Surgical drainage may comprise standard incision and drainage of an orofacial swelling or, in the case of localized periapical infection, endodontic drainage through the pulp or extraction of the offending tooth.

Surgical treatment of odontogenic infections is primary. In a systematic review of the literature, Flynn concluded that once an abscess was drained, the usual antibiotics used for treatment of odontogenic infections worked.^{27,28} Dodson and colleagues,²³ in a review of head and neck infections requiring hospitalization of children, found that facial infections of the regions at or above the level of the upper lip and teeth most frequently were upper respiratory tract- or sinus-related and that lower face infections primarily were odontogenic. Infections of the upper face resolved without surgery in 65% of cases, whereas infections of the lower face resolved without surgery in only 25% of cases. Odontogenic infections almost always required some sort of surgical intervention. This finding may be due to the fact that the portal of entry in respiratory tract infections is through the surface mucosa, whereas the tooth roots carry the invading bacterial pathogens deep into the bone of the jaw, through which the surrounding deep fascial spaces become infected.

Respiratory pathogens frequently are viral, and odontogenic infections almost uniformly are bacterial, which may explain the propensity of odontogenic infections to form abscesses that need to be drained. Odontogenic infections treated with antibiotics only almost always recur in worse form than their previous manifestation. The indications for treating with antibiotics in addition to appropriate dental surgical therapy are fever, trismus, lymphadenopathy, osteomyelitis, and compromise of the immune system. Minor infections localized to the alveolar processes can be treated by tooth extraction, gingival curettage, or root canal therapy, with or without intraoral incision and drainage, without the use of antibiotics in the nonimmunocompromised individual.

Approximately 10% of all antimicrobials prescribed in the community are for the treatment of an oral process.¹⁸ Misuse and overuse of antimicrobials have led to increasing resistance among many bacterial species. Oral pathogens have not been the exception. In an effort to promote the judicious use of antibiotics, the American Academy of Pediatric Dentistry (AAPD) and American Dental Association have developed guidelines intended to help reduce the inappropriate use of antimicrobial therapy in oral infections.¹ Despite the guidelines, the adherence to the recommendations continue to be low, as demonstrated in a recent survey of 154 dentists revealing that adherence to guidelines was between 10% and 40%.¹⁸ In these guidelines, consideration for treatment with antibiotics involves the assessment of certain factors such as the type of infection, location and extent of infection, risk for bacterial contamination (e.g., deep crown fractures), trauma, and immunologic status of the patient.

Selecting the appropriate antibiotic should follow the basic principles of therapeutics, which include choosing the narrowest spectrum based on cultures and susceptibilities and selecting an agent that concentrates adequately in the desired tissues and that has a good safety profile, convenient dosing, and the fewest side effects. In addition, it is important to inquire about the patient's previous antimicrobial exposures, which is a known risk factor for harboring more resistant organisms, as well as documentation of any drug allergies. In the adolescent population, asking about oral contraceptives is important because certain antibiotics used to treat dental infections, such as penicillins and tetracycline derivatives, can interfere with the efficacy of contraceptives.¹

Antibiotic selection for odontogenic infections, although ultimately based on Gram stain and aerobic and anaerobic cultures, generally is begun empirically before culture results are available. Odontogenic infections are usually polymicrobial, with anaerobes playing an important role.¹² Penicillin and amoxicillin have been the first choice for outpatient infections on the basis of a good safety profile, bactericidal nature, and sensitivity of most streptococci and oral anaerobes to penicillin. However, there have been more reports of penicillin and amoxicillin resistance among oral pathogens that produce β -lactamases. Moreover, penicillin offers little or no coverage against *Neisseria* spp., a pathogen frequently

found in odontogenic infiltrates.⁸⁸ A study of hospitalized patients with odontogenic infections found penicillin-resistant organisms in 54% of cases and therapeutic failure of empiric penicillin in 21% of cases.²⁸ The duration of previous therapy with β -lactam antibiotics also has been correlated with increased numbers of β -lactamase-producing bacteria in persisting infections. Patients with persisting infection after 3 days of treatment with a β -lactam antibiotic had a 50% incidence of β -lactamase-producing bacteria in the infection.^{40,49} β -Lactamase inhibitors used in combination with β -lactam antibiotics may improve their effectiveness against resistant anaerobes, and using higher doses of the amoxicillin component may overcome resistance of some oral streptococci.⁹

Antibiotic susceptibility studies indicate that the oral anaerobes (especially *Fusobacterium*) and *Streptococcus* spp. now are largely resistant to erythromycin.^{35,77,79} Based on these data, erythromycin should not be used as first choice in patients with odontogenic infections who are allergic to penicillin. Clindamycin, on the other hand, has an excellent track record in the treatment of odontogenic infections and can be used in patients allergic to penicillin. It concentrates well in saliva and bone and has enhanced activity against anaerobes, including bacteroides. However resistance of odontogenic flora to this lincosamide derivative is also on the rise. Poeschl and colleagues⁸⁰ tested 73 streptococci species isolated from patients with odontogenic deep-space infections and found 16% clindamycin resistance among *Streptococcus* spp. and 11% resistance among oral anaerobes (*Prevotella*, *Bacteroides*, and *Peptostreptococcus* spp.). *Eikenella corrodens*, an occasional pathogen in odontogenic infections, is uniformly resistant to clindamycin, which may explain the lack of effectiveness of clindamycin in some cases. A feared complication of the use of clindamycin is the development of *Clostridium difficile* colitis. This entity was first described after the use of this antibiotic and has been reported after use of clindamycin as prophylaxis for dental infections.¹¹ However, more cases are reported yearly of *C. difficile* after the use of penicillin and cephalosporins than with clindamycin.¹² Penetration of this drug through the blood-brain barrier is poor, and it should not be used to treat central nervous system abscesses of odontogenic origin. Azithromycin is another alternative in patients with severe penicillin allergies. It has comparable activity against oral gram positives but enhanced coverage for anaerobic gram negatives when compared to erythromycin, and it has been utilized successfully in the treatment of adult patients with periodontal disease.^{43,69}

Moxifloxacin, a fluoroquinolone with a spectrum of activity similar to that of amoxicillin-clavulanate, has been studied for the treatment of odontogenic infections with very good outcomes. A double-blind, phase II randomized trial comparing moxifloxacin with clindamycin in odontogenic infections found that moxifloxacin has excellent activity against *Streptococcus* spp. and oral anaerobes and was very effective in treatment of inflammatory odontogenic infections and abscesses.¹⁴ However, this trial did not include children. Fluoroquinolones, especially ciprofloxacin and levofloxacin, have been used more often in children in recent years, especially in those with cystic fibrosis. The concern of musculoskeletal adverse events (e.g., tendinitis or adverse cartilage effects) has always been the limiting factor for their use in children. Ciprofloxacin and levofloxacin are less active against oral pathogens. Moxifloxacin has been used successfully in the treatment of multidrug-resistant tuberculosis in children.^{5,17,30,99} Yet the optimal dosing remains to be determined. A recent pharmacokinetic study of moxifloxacin in children with tuberculosis showed that using a 10 mg/kg daily dose achieved low serum concentrations when compared to the maximum 400 mg daily adult dose, suggesting that perhaps higher doses are needed.⁹⁹

The second-line antibiotics in odontogenic infections are the cephalosporins, which, with the exception of the cephamycins (i.e., cefoxitin, cefotetan), have poor activity against oral anaerobes. Cephalosporins can be combined with metronidazole to enhance anaerobic coverage. Metronidazole has excellent activity against anaerobic bacteria but no activity against aerobic organisms. Moreover, it has no activity against organisms such as *Actinomyces* and microaerophilic streptococci, thus limiting its use as monotherapy for odontogenic infections.⁵⁴

Tetracycline is incorporated permanently into newly formed dentin, causing permanent disfiguring discoloration of the dentition. It should not be used in children until they are at least 9 years old, when all but the third molar teeth would have full crown formation.

TABLE 8.3 Empiric Antibiotics of Choice for Odontogenic Infections

Type of Infection	Antibiotic of Choice
Outpatient infections	Penicillin Clindamycin
Penicillin allergy	Clindamycin Azithromycin
Inpatient infections	Clindamycin Ampicillin + metronidazole Ampicillin + sulbactam
Penicillin allergy	Clindamycin Third-generation cephalosporin IV (if the penicillin allergy was not the anaphylactoid type—use caution) + metronidazole

Empiric antibiotic therapy is used before culture and sensitivity reports are available. Cultures should be taken in severe infections that threaten vital structures.

Penetration into the blood-brain barrier is important when treating odontogenic infections that spread beyond the oral cavity and approach the cranial cavity. Penicillin will penetrate the barrier when the meninges are inflamed, whereas first- and second-generation cephalosporins will not. Clindamycin has poor penetration into the central nervous system and should not be used in brain abscesses. Conversely, metronidazole has excellent central nervous system penetration but needs to be combined with treatment for aerobic bacteria.⁵⁴

The aforementioned considerations suggest that the empiric antibiotics of choice are penicillin in mild odontogenic infections and clindamycin for severe cases or in a patient with penicillin allergy. Table 8.3 lists our recommendations for empiric antibiotic therapy in odontogenic infections.

Nursing Bottle Caries

Nursing bottle caries is a pattern of tooth decay affecting mainly the primary upper incisors and frequently the upper and lower primary molars in children of bottle-feeding age. It is caused by a practice of putting the child to bed with a nursing bottle filled with a sugar-containing drink, such as milk, fruit juice, or a soft drink. The child sucks on the bottle intermittently during sleep, when salivary secretion is low, and the sugar-containing liquid stays in the mouth for extended periods. This situation provides an excellent environment for the growth of caries-producing organisms such as *S. mutans*. Nursing bottle caries can destroy virtually the entire primary dentition of a child as it erupts. Pediatric physicians and dentists should instruct parents to avoid putting their children to bed with nursing bottles or, if they must do so, to use water only in the bedtime drink.

Periapical Abscess

Extension of microorganisms through the root apex leads to the formation of an abscess. Early in this process, the acute abscess is indistinguishable clinically and radiographically from an acute pulpitis, particularly because radiographic evidence of bone destruction may take 7 to 14 days or more to develop. Sensitivity to heat stimulus (relieved by cold), exquisite sensitivity to percussion, and tenderness to finger pressure on the alveolar process are indications that the tooth has become abscessed. Electric pulp testing may be diagnostic if the tooth shows no response to the electric stimulus, but a positive pain response may be equivocal in multirrooted teeth. Chronic abscesses are diagnosed more easily by looseness of the tooth, suppuration from draining sinuses or gingival crevice (see Fig. 8.3), and radiolucency on the radiographs (see Fig. 8.1). Depending on the path of least resistance, fluctuant areas may be noted in the buccal or lingual mucosa. Spread through the tissues, or cellulitis, may lead to the classic presentation of swollen face, pain, elevated temperature, and malaise.

In 1951, Krogh⁴⁹ showed a 3% complication rate when 2626 infected teeth were removed at the time of initial presentation. In 1975, Martis and Karakasis⁶⁵ published a similar study in which they treated 1376

FIG. 8.7 (A) Normal gingivae. (B) Severe gingivitis. The maxillary gingivae exhibit mild inflammation; the mandibular interdental papillae are distorted grossly in form. Accumulations of plaque are prominent adjacent to the mandibular incisors. (C) Acute necrotizing ulcerative gingivitis.

BOX 8.1 Indications for Antibiotic Therapy in Odontogenic Infections

Antibiotic Therapy Is Necessary

Acute-onset facial or oral swelling
Swelling inferior to the mandible
Trismus
Dysphagia
Lymphadenopathy
Fever $>38.3^{\circ}\text{C}$ ($>101^{\circ}\text{F}$)
Pericoronitis
Osteomyelitis

Antibiotic Therapy Is Not Necessary^a

Asymptomatic periapical abscess
Parulis (draining sinus tract)
Dry socket (alveolar osteitis)
Periodontal disease
Dental extractions
Root canal therapy

^aWith coexisting immune system compromise, antibiotic therapy may be indicated in some of these conditions.

acute dentoalveolar abscesses by immediate extraction. A 3% complication rate was found in this study as well. A complication was defined as further extension of the infection requiring additional treatment. Hall and associates³⁹ published a report in 1968 in which 350 patients with odontogenic cellulitis were divided randomly into two groups. The first group had extractions performed on the day of initial presentation, whereas the second group waited (with antibiotics) until the fourth day for surgical treatment to be performed after “localization” had occurred. The investigators’ observations showed that extraction did not spread the cellulitis in either group. Patients with earlier extractions recovered more rapidly, whereas patients with delayed treatment had a greater need for incision and drainage, which was twice as likely to be extraoral than intraoral. In 1978, Martis and colleagues⁶⁵ showed in a series of more than 2000 patients that extraction without antibiotics in the presence of periapical infection led to the same complication rate as did extraction of noninfected teeth. Current literature validates these earlier findings, indicating that infections in patients with poor oral health and a lack of preceding dental treatment produce a stronger systemic response. Extraction of involved teeth when indicated and other dental treatments lead to a less severe course of infection.⁹¹

Considering the prospect of early relief of symptoms and a 97% chance that extraction (or occasionally root canal treatment) will cure the infection, early surgical intervention is mandatory. The use of antibiotics must be determined on an individual basis according to principles outlined previously (Box 8.1).

Periodontal Infections

Surrounding the teeth is a distinctive, pink keratinized mucosa, the gingiva (Fig. 8.7A). Normal gingiva is attached firmly to the alveolar bone and extends between the teeth as the interdental papilla. A thin cuff of free (nonattached) gingiva surrounds each tooth, and the resulting crevice between the free gingiva and the tooth normally is 1 to 3 mm in depth. It is represented by a thin roll of tissue along each tooth in Fig. 8.7A.

Accumulation of food deposits and bacteria in the gingival crevice may result in gingivitis, a localized inflammation of the free gingiva that manifests as an erythematous, nonpainful swelling of the interdental papillae. In severe cases (see Fig. 8.7B), the gingival architecture may become distorted, and accumulations of plaque are evident. Although gingivitis is prevalent at all ages, affecting more than 50% of children⁶⁷ and almost all adults to some degree, it often is most severe in compromised hosts, including patients with diabetes and immunosuppressed patients. Poor oral hygiene is the usual precipitating factor for the development of gingivitis, and this condition generally responds to dental scaling and improved oral hygiene.

In adolescents and adults, gingivitis may progress to periodontitis, a progressively severe infection characterized by hypertrophied gingivae, tooth mobility caused by irreversible resorption of alveolar bone, and a purulent exudate. This insidious condition usually is painless and may progress for years before being recognized. Localized periodontal treatment and meticulous oral hygiene may arrest the condition.

A rare variant, juvenile periodontitis,⁵³ usually is localized to the molar and incisor regions of younger, otherwise healthy children. Deep gingival pocketing and severe bone resorption are characteristic of this process and may result in loss of the dentition in these areas. The etiology is thought to involve a gram-negative anaerobe, *A. actinomycetemcomitans*, and localized bacterial inhibition of leukocyte function. Tetracycline in older patients has been useful in combination with periodontal surgery and meticulous home care.

Acute necrotizing ulcerative gingivitis (see Fig. 8.7C) is a specific infection caused by fusiform bacilli and spirochetes. Synonyms include trench mouth and Vincent infection. Erythema at the tips of the interdental papillae soon is supplanted by frank ulceration and foci of spontaneous bleeding. A pseudomembranous necrotic exudate forms along the marginal gingivae and the interdental papillae. The papillae later become blunted. Acute necrotizing ulcerative gingivitis is characterized by pain, foul breath and taste, thick ropy saliva, malaise, and occasionally fever. Theories suggest a concomitant viral etiology. Treatment consists initially of penicillin or amoxicillin \pm metronidazole therapy for 7 days followed within a few days by localized gingival curettage and oral rinses with 0.5% hydrogen peroxide or 0.12% chlorhexidine.^{4,49,60}

Pericoronitis

Impaction of microorganisms and debris under the soft tissue overlying the crown of a tooth, often a mandibular third molar, or any erupting permanent tooth leads to the development of inflammation. Drainage usually occurs spontaneously from under the flap, localizing the problem.

FIG. 8.8 Pericoronitis.

Blockage of natural drainage may lead to spread of infection to adjacent soft tissues and fascial spaces (Fig. 8.8).

Pericoronitis is a polymicrobial infection; the periodontal pathogens *Prevotella* and *Porphyromonas* spp. and oral spirochetes, such as *Treponema denticola*, usually are the causative organisms. The *Streptococcus milleri* group bacteria also have been found to have a significant role in acute pericoronitis.⁴² These organisms usually are sensitive to penicillin or penicillin combined with metronidazole. Pericoronitis most frequently occurs around the posterior portion of the crown of the lower third molar because it erupts during adolescence. In most cases, partial eruption of the third molar is caused by insufficient length of the horizontal ramus of the mandible to house all of the teeth. Part of the third molar is trapped under the oral mucosa covering the buccinator muscle and the superior pharyngeal constrictor because they form the most anterior portion of the oropharynx. In cases in which room is insufficient for the eruption of the third molar, the pericoronitis becomes recurrent or chronic, and the impacted third molar should be removed.

Lower third molars lie in proximity to the pterygomandibular space, a portion of the masticator space. When these infections spread to involve this space, trismus results, which obscures the infection to clinical examination. The presence of trismus with a history of pain in the third molar region is an ominous sign of infection involving the masticator space, which, although not manifested by external facial swelling, may begin to involve the deeper parapharyngeal spaces. These infections may become life-threatening. The lower third molar is the most frequent offending tooth in severe odontogenic infections requiring hospitalization, and these infections occur most frequently in adolescents and young adults.⁴¹

Various treatment modalities, including local incision and drainage and extraction of the tooth, are applicable to pericoronitis.^{64,87} Antibiotic therapy is used if fever, trismus, or lymphadenopathy is present (see Box 8.1). Resolution of symptoms should occur in less than 1 week.

Oral Manifestations of Human Immunodeficiency Virus Infection in Children

The most common oral lesions in children with human immunodeficiency virus (HIV) disease are oral candidiasis, herpes simplex virus (HSV) infections, linear gingival erythema, parotid salivary gland enlargement, and recurrent aphthous ulcerations. In contradistinction to adult HIV infection, HIV-associated periodontitis and gingivitis are much less common. Neoplastic oral manifestations of HIV infection, such as Kaposi sarcoma, non-Hodgkin lymphoma, and hairy leukoplakia,

continue to be rare findings. In contrast to adults, children infected with HIV have a greater susceptibility to bacterial infections, especially with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Septicemia from an oral focus of infection can become a life-threatening problem in an HIV-infected child, and optimal oral health must be established and vigorously maintained in these children.⁵¹ Routine use of chlorhexidine gluconate 0.12% mouth rinse may be helpful in minimizing gingivitis, candidiasis, and bacterial superinfections of the oral cavity, although its safety and effectiveness have not been shown in children.

Oral candidiasis usually is of the pseudomembranous type, which is seen in the oral cavity as a creamy white plaque that is rubbed off easily, leaving a reddened surface mucosa exposed. Because oral candidiasis is rare in normal children older than 6 months, persistence of oral candidiasis for 2 months or more in a child older than 6 months who has not received antibiotic therapy in the past 2 weeks is suggestive of HIV infection. Persistent oral candidiasis indicates acquired immunodeficiency category P-2D3 (symptomatic infection with secondary infectious diseases) in the Centers for Disease Control and Prevention classification of HIV infection in children younger than 12 years.⁴⁸

Oral candidiasis was associated with a decreased survival time in a study of 99 children with perinatally acquired HIV infection. The median time from birth to the manifestation of the first lesion of oral candidiasis was 2.4 years, and the median time from the appearance of lesions to death was 3.4 years, with a relative hazard rate of 14.2.⁴⁷

Treating oral candidiasis lesions is difficult because of frequent recurrence of oral fungal infection with resistant biotypes of *Candida albicans* or colonization by related but more resistant species such as *C. krusei*, *C. parapsilosis*, and *C. guilliermondii*. Treatment regimens range from nystatin to clotrimazole for uncomplicated oropharyngeal candidiasis to fluconazole, other azoles, echinocandins, or amphotericin B for more severe disease depending on the extent of disease, clinical response, and culture and sensitivity results.^{51,62,75,76} Sudden onset of rampant dental caries has been associated with prolonged oral use of sucrose-containing antifungal antibiotic preparations.⁸⁵

Linear gingival erythema, formerly referred to as HIV gingivitis, is the most common form of periodontal disease seen in children with HIV infection. It is described as a fiery red, 2- to 3-mm-wide linear band of inflammation of the gingiva. Pain is not associated with the lesion, but the gingivae are likely to bleed during toothbrushing or even spontaneously. The microbiology of this lesion is unclear, but *Candida* spp. may be a possible cause.

Parotid salivary gland enlargement, which may be painful and become secondarily infected, has been reported in 14% to 30% of HIV-infected children. The enlargement apparently is caused by infiltration of the glands by T8 lymphocytes and has been associated with increased survival time. The median time was 4.6 years from birth to development of parotid enlargement and 5.4 years from development of lesions to death, with a relative hazard rate of 0.38.⁴⁷

Herpes simplex virus infections, although common occurrences in normal children, seem to be particularly severe and recur more often in HIV-infected children. The lesions appear first as multiple clustered vesicles on the lips or keratinized oral mucosa, which soon rupture to leave painful irregular oral ulcers or crusted labial ulcers. Fever and dysphagia may warrant hospital admission for hydration, nutrition, and therapy with parenteral acyclovir. Less severe cases may be treated with oral acyclovir.

Dental caries is increased in pediatric HIV cohorts. The cause of this finding is unclear. It may be due to xerostomia secondary to parotid enlargement in some cases, prolonged use of sucrose-containing antifungal agents in others, and nursing bottle caries in still others. The association of nursing bottle caries with pediatric HIV infection may be due to their common increased prevalence in urban dwellers with limited economic resources, although nursing bottle caries also is found frequently in children with other chronic diseases.¹⁰²

ORAL CARE OF CHILDREN WITH CANCER

Chemotherapy and other therapies such as radiation can exert a profound, detrimental, and sometimes long-lasting effect on the oral mucosa. In

the presence of diminished immune function, the oral cavity becomes an important potential source of infections in these patients, and therefore careful attention to their oral and dental health is pivotal. This has been recognized by the AAPD, which adopted guidelines in 1986 regarding the dental management of patients receiving chemotherapy, radiotherapy, or a hematopoietic stem cell transplant (HSCT).^{3,9} The care of the oral cavity begins before patients are subjected to these therapies. Initial evaluation by dentistry is a must to identify and eliminate any potential sources of infection and to educate the patients and parents on the importance of oral health during their cancer treatment. Patients are encouraged to brush teeth and tongue at least 2 or 3 times daily with regular soft nylon brushes, and, in cases of poor hygiene, to use alcohol-free chlorhexidine solutions. Many of these patients have indwelling central catheters at the time that dental care is being performed. Still, data at this time do not support the use of antibiotic prophylaxis in these patients when the absolute neutrophil count (ANC) is above 2000/mm³. If the ANC falls between 1000 and 2000/mm³ and planned dental procedures are scheduled, some authors suggest that prophylaxis at doses recommended by the American Heart Association for valvular devices may be of benefit.^{3,6,44,52,74} This decision should be taken alongside the oncology team. Extractions of teeth that are found to be infected should be treated with a short course of antibiotics (7 days after extraction), ideally tailored to susceptibility of the organisms isolated in culture.

In patients undergoing HSCT, all elective procedures need to be completed before the start of the conditioning regimen because the prolonged immunosuppression that these patients face will not allow for any elective procedure until at least 100 days post transplantation.

Once patients enter those periods in which neutropenia ensues, they should continue teethbrushing at the same frequency as before. If the patient develops mucositis and cannot tolerate the soft toothbrush, foam brushes or super-soft brushes can be used, acknowledging that these alternatives do not provide optimal cleaning. Flossing may be continued if this was routine for the patient previously and care is exercised. Only emergency dental procedures should be performed when the ANC is less than 1000/mm³ and should be performed in the inpatient setting with a multidisciplinary approach because supportive therapies such as blood products, antimicrobials, and analgesia may need to be provided.^{3,6,44,52}

There is a well-established association between oral mucositis and bacteremia in cancer patients.^{3,6,44,52} A recent study by Flagg et al.²⁶ examined the associated characteristics of bacteremia in pediatric oncology patients based on whether the organism was a commensal to the mouth, gastrointestinal tract, or skin. Having a bacteremia with oral pathogens (e.g., *S. viridans*) was associated with the presence of mucositis and with lower platelet counts, ANC, and hemoglobin. An ANC of less than 500/mm³ was significantly associated with bacteremia with oral flora versus other organisms.²⁶ Palifermin is a keratinocyte growth factor that has been approved by the U.S. Food and Drug Administration for the prevention of mucositis in adult patients with hematologic malignancies; however, there are scant data at this time regarding its safety and benefit in the pediatric population.^{44,21,104}

As in children with HIV, herpetic infections are common and usually are the result of reactivation. Patients who are HSV seropositive prior to HSCT are routinely started on prophylaxis at the time of conditioning and continued well into the postengraftment period. Despite prophylaxis, breakthrough infections occur and may be difficult to recognize because they are frequently confused with mucositis, graft versus host disease, or medication side effect (i.e., oral ulcers associated with foscarnet) among other. Therefore a high index of suspicion must be maintained.

Candida spp. can cause superficial and deep infections in cancer patients, especially at the time of neutropenia. Most centers will provide prophylaxis to patients undergoing HSCT because periods of prolonged neutropenia are anticipated.¹⁰⁰ Treatment of oral candidiasis will depend on the severity of the infection. For mild disease, topical therapy with clotrimazole troches or nystatin suspension can be used, whereas more severe symptoms require the use of systemic therapy. Updated guidelines for the treatment of *Candida* are now available.⁷⁶ Other fungal infections that may present in the oral cavity include mold infections, especially

Aspergillus, which can extend from the sinuses into the oral cavity or by hematogenous spread. Therefore any unusual-appearing lesion (e.g., white, dark, erythematous lesions or solitary ulcers) or lesions that fail to heal in the oral cavity should be thoroughly evaluated because they may be fungal in origin.^{52,74}

COMPLICATIONS OF ODONTOGENIC INFECTIONS

Fascial Space Infections

Spread of infection to the fascial spaces may result in dramatic facial swelling, high fever, and, if untreated, respiratory compromise. The characteristics of the more common fascial space infections related to odontogenic infection are described in this section.

Infraorbital space infections generally are related to maxillary anterior teeth and are well localized to the infraorbital fossa by the levator labii superioris and levator anguli oris muscles. Facial swelling lateral to the nose is prominent, as is decreased mobility of the upper lip caused by inflammation of these muscles. If the area is fluctuant, intraoral incision and drainage with placement of a small Penrose drain for 1 or 2 days generally is sufficient treatment. Antibiotics are indicated for all infections of the fascial spaces.

Trismus is the hallmark of infection of the masticator space. Trismus is caused by spasm in the muscles of mastication, which define this large potential space. The resulting inability to open the mouth hinders access to the airway for endotracheal intubation. In addition, abscesses of the masticator space may rupture into the oropharynx, causing aspiration of pus, or they may pass easily around the medial pterygoid muscle to involve the lateral pharyngeal and retropharyngeal spaces. Fig. 8.9 shows a 6-year-old boy whose lower primary molar abscesses spread to involve the buccal, pterygomandibular, and lateral pharyngeal spaces. Extraoral and intraoral drainage, prolonged intubation, and extraction of the offending teeth were required.

Infections of the submandibular space (Fig. 8.10) may be localized unilaterally or may involve bilateral structures. Treatment of submandibular space infection is via extraoral incision and drainage.

First described in 1836, Ludwig angina consists of infection of the sublingual and submandibular spaces bilaterally and is characterized by hard, brawny swelling and a minimum of suppuration. The tongue often is edematous and raised to the roof of the mouth, with little mobility (Fig. 8.11). Airway obstruction should be considered imminent; the greatest cause of death in Ludwig angina is blockage of the airway by soft tissue swelling, pus, or blood, which occurred in more than 50% of its victims in the preantibiotic era.³⁸ In 1940, Williams¹⁰⁷ published a series of 37 cases of Ludwig angina that reported a 54% mortality

FIG. 8.9 Lateral pharyngeal space abscess in a 6-year-old boy. Note the swelling above the hyoid bone and anterior to the sternocleidomastoid muscle. Swelling also occurs in the buccal and submandibular spaces.

FIG. 8.10 Submandibular space abscess.

FIG. 8.11 Ludwig angina.

rate. The airway management policy at that time was emergency tracheotomy if necessary. Three years later, Williams and Guralnick^{107,108} published a series of 20 cases of Ludwig angina treated with a new policy of immediate establishment of airway security by intubation or tracheotomy and aggressive incision and drainage of all anatomic spaces affected by the infection. By these measures, they were able to reduce the mortality rate of this dreaded infection to 20% only 3 years later. Antibiotics were unavailable during the course of these two studies. These studies underscore the importance of airway security and aggressive surgical management in the treatment of severe odontogenic infections.

Today death rarely occurs from severe odontogenic infections, although the need for tracheotomy or prolonged endotracheal intubation is common. The cause of this infection often is odontogenic infection but may include laceration of the floor of the mouth and mandibular fracture. Usually a disease of middle-aged adults, it is a rare occurrence in children but may occur in greater frequency in immunologically compromised children.³⁴ Surgical drainage of all four spaces, accompanied by vigorous antibiotic therapy, is indicated.

Necrotizing Fasciitis

Necrotizing fasciitis, which causes a frightening loss of skin and underlying tissues, has received considerable notoriety in the press. Cervicofacial necrotizing fasciitis often is odontogenic and typically causes a superficial spreading of cellulitis that follows the platysma muscle from the cheek down the entire neck to the anterior chest wall (Fig. 8.12A). Fig. 8.12B illustrates such a swelling in an 8-year-old boy. The presumptive cause was odontogenic infection of the primary molars, which caused a high fever and a rapidly progressive cellulitis extending from the cheek to the chest. The cause of these infections often is group A streptococci, but a wide variety of microorganisms may be involved.

Wide-spectrum antibiotic therapy is indicated empirically, along with hydration, transfusions if necessary, and support of electrolyte balance, especially with calcium, which may be sequestered by necrotic fat molecules.⁷ Timely surgery is important in the management of necrotizing fasciitis. Incision and drainage of the involved spaces, debridement of necrotic tissue, and fasciotomy often are performed as soon as possible after the patient's admission.¹⁰⁶ Hyperbaric oxygen therapy has been advocated as an adjunct in the treatment of necrotizing fasciitis. A significant reduction in the mortality rate and length of hospitalization associated with necrotizing fasciitis has been shown in adults.¹⁰⁶ Necrotizing fasciitis is cited as an indication for hyperbaric oxygen therapy in infants and children and should be considered if available.¹⁰⁵

Odontogenic Sinusitis

A significant percentage of cases of sinusitis are odontogenic, especially in adults, because the maxillary sinus follows the erupting permanent tooth roots into the alveolar process. This pneumatization of the alveolar process progresses throughout life and is accelerated by loss of the upper posterior teeth. Dental infections of the periapical upper posterior teeth occasionally rupture through the maxillary sinus floor to involve the paranasal sinuses. Dental infection should be eliminated in the complete treatment of severe recurrent sinusitis in children.

Fig. 8.13 illustrates a case in a 9-year-old boy of left pansinusitis, including ethmoiditis and a subperiosteal orbital abscess associated with infected upper primary molars. His treatment involved a team approach of the dental and otolaryngology services for tooth extraction, incision and drainage of the buccal and infraorbital spaces, endoscopic sinus surgery, and external drainage of the orbital abscess.

Buccal and Periorbital Cellulitis

A child occasionally presents with an acute buccal or periorbital space swelling and cellulitis with no clinically apparent odontogenic cause. These infections tend to occur in young children, usually younger than 36 months. They usually have a history of recent upper respiratory infection or sinusitis. *H. influenzae* type b and *S. pneumoniae* have been implicated as pathogens in these conditions, although the widespread use of conjugated vaccines has reduced dramatically the incidence of invasive disease from *H. influenzae*.³³ A possible mechanism for the inoculation of the soft tissues is migration of organisms through emissary veins piercing the thin cortical bone overlying the lateral surface of the maxillary sinus in cases with existing sinusitis. Unless the infection is severe, incision and drainage usually are unnecessary, and treatment with antibiotics is successful. Blood cultures frequently are positive in more severe cases. The role of lumbar puncture remains controversial in the overall management of infants and young children. The incidence of this infection has declined significantly as a result of the widespread use of *H. influenzae* vaccine.

Orbital and Intracranial Complications

Odontogenic infections that spread to involve the orbit and the brain are rare. Orbital and intracranial abscesses may have an odontogenic origin; however, and the dental condition of patients with these conditions should be evaluated by a dentist. Probably no more than 5% to 10% of orbital cellulitis is odontogenic in origin.^{46,109} This infection generally is unilateral and is characterized by proptosis, chemosis, lid edema, and restriction of extraocular motion secondary to edema.⁸² No nerve palsies or visual changes are present. Treatment includes surgical drainage, antibiotics, and elimination of the dental infection.

FIG. 8.12 (A) Surgical debridement of necrotic skin and platysma muscle of the left neck of a diabetic female patient with necrotizing fasciitis. Note how easily blunt finger dissection can undermine the skin in the plane of the necrotic platysma muscle. (B) Necrotizing fasciitis in an 8-year-old boy. Note the swelling extending from the buccal space down the neck and onto the anterior chest wall, following the extent of the platysma muscle. The chalky material on the posterior neck is calamine lotion placed by the patient's mother for vesicles that resembled poison ivy.

FIG. 8.13 (A) A 9-year-old boy with a left pansinusitis and an abscess of the upper left first primary molar. Note the left periorbital discoloration and swelling, with partial ptosis and displacement of the globe laterally. (B) Computed tomography scan of the same patient. Note the left maxillary sinus opacification close to the infected tooth, opacification of the ethmoid sinuses, elevation of the periosteum away from the medial orbital wall, and displacement of the globe laterally within the orbit.

Cavernous sinus thrombosis, which may be difficult to differentiate clinically from orbital cellulitis, is considerably more serious because microorganisms proliferate intracranially. The risk for death is high. Characteristics include bilateral involvement with rapid progression from one eye to the other, proptosis, chemosis, and lid edema. Extraocular movements are limited because of inflammation of the third, fourth, and sixth cranial nerves. Systemic signs of meningeal irritation and ophthalmoscopic evidence of obstruction of the retinal veins also are present.^{19,82,97} Treatment includes high doses of parenteral antibiotics, elimination of the causative dental pathosis, and incision and drainage of infected fascial spaces. Odontogenic cavernous sinus thrombosis seems to be propagated by an ascending thrombophlebitis.

Brain abscess and subdural empyema are rare findings today compared with several decades ago. Dental sources of infection have been implicated in brain abscesses from less than 1% to 8.5% of cases reported.^{15,81,85,94} Odontogenic brain abscesses seem to occur by direct extension through the paranasal sinuses, usually to the frontal lobe through the frontal sinuses. Typically a pansinusitis intervenes between the dental infection and the brain; however hematogenous and contiguous anatomic routes of spread are possible.^{50,61,90} The literature supports the fact that oral flora are found in brain abscesses, but a correlating culture from the supposed oral source is rarely found, often making brain abscess secondary to dental infection a diagnosis of exclusion.⁴⁰

OSTEOMYELITIS OF THE JAWS IN CHILDREN

Osteomyelitis of the jaws in children usually results from periodontal or, more commonly, periapical infection. Open fracture of the jaws with delayed treatment also is a significant cause of osteomyelitis. Extension from contiguous infections, such as otitis, parotitis, and mastoiditis, occurs much less often.

Osteomyelitis of the jaws occurring in children must be viewed with great concern because it may result in (1) loss of primary and permanent teeth; (2) sequestration of segments of the jaws; (3) growth defects, such as mandibular hypoplasia, asymmetry, and ankylosis²⁵; (4) disfiguring facial scars and cutaneous fistulas; and (5) lesions suggestive of malignancy, which require open biopsy. For these reasons, osteomyelitis of the jaws in children should be diagnosed rapidly and treated aggressively. [Box 8.2](#) presents a useful classification of this disease.¹⁰¹

Predisposing Factors

Preexisting systemic disease with accompanying alteration of host resistance plays a major role in the initiation of osteomyelitis of the jaws. It includes conditions such as uncontrolled diabetes, agranulocytosis,

Radiation osteomyelitis and necrosis

leukemia, sickle-cell disease, and febrile illnesses. Conditions that alter the vascularity of bone and the ability to combat infections, including bone tumors, fibrous dysplasia, Paget disease, and radiation to the jaws, also are important predisposing conditions. Major maxillofacial injuries resulting in open fractures of the jaws, especially fractures that are not treated immediately, are an important cause of osteomyelitis.

Microbiology

Because the etiology of osteomyelitis of the jaws includes causes other than purely odontogenic infections, the bacterial spectrum is broad. Most instances of osteomyelitis of the jaws are caused by aerobic streptococci (α -hemolytic streptococci and *S. viridans* group), anaerobic streptococci, and other anaerobes, particularly *Peptostreptococcus*, *Fusobacterium*, and *Bacteroides* and related genera.⁷⁷ Only occasional cases are caused by *S. aureus*, with entry through the skin being the probable route. Other bacteria involved include oral anaerobes, aerobic and microaerophilic cocci, and gram-negative organisms. Specific forms of osteomyelitis are caused by *Actinomyces israelii*, *Treponema pallidum*, and *Mycobacterium tuberculosis*. *Salmonella* organisms have been associated with osteomyelitis of the jaw in patients with sickle-cell anemia.²²

Clinical Findings

Osteomyelitis involves the mandible far more frequently than the maxilla because the poor blood supply to the mandible comes primarily from one major vessel and the periosteal blood supply. Four major forms of the disease, which may be distinguished clinically, are (1) acute suppurative; (2) secondary chronic, which begins as an acute osteomyelitis and becomes chronic; (3) primary chronic, which has no acute phase and always has seemed to be a low-grade infection; and (4) nonsuppurative osteomyelitis. The forms most often seen in children are the acute suppurative, the secondary chronic, and one nonsuppurative form: Garré sclerosing osteomyelitis. These conditions are described in some detail.

Suppurative Osteomyelitis

Suppurative osteomyelitis usually begins with deep and intense pain in the jaws, high intermittent fever, and an obvious cause, most often a deeply carious or discolored tooth. In the early stages, mental nerve paresthesia occasionally is present. During the course of several days, facial swelling develops, and in 10 to 14 days, teeth begin to loosen, pus exudes around the gingival sulcus, and multiple mucosal or cutaneous sinus tracts form. In addition to the draining sinuses, a firm cellulitis is present in the soft tissues, accompanied by trismus and cervical lymphadenopathy. A leukocytosis, ranging typically from 8000 to 15,000 cells/mm³, is present, although it does not ordinarily reach the levels seen in acute osteomyelitis of the long bones. After 10 days to 2 weeks, radiographs may show scattered areas of bone destruction with a moth-eaten appearance (Fig. 8.14), and periosteal reaction characterized by the laying down of new bone commonly is seen. Smears of specimens and cultures, including cultures of bone sequestra, should be taken whenever possible. Interpretation of cultures must be made with caution because of the possibility of skin and oral contaminants in the specimen.

Initially, antibiotic doses adjusted for age may be given empirically, but the selection of the antibiotic is determined by culture and sensitivity testing of specimens taken directly from the infected site.³¹ The antibiotics of choice in mandibular osteomyelitis include amoxicillin-clavulanate, clindamycin, and fluoroquinolones. Fluoroquinolones are excellent choices because of their complete absorption from the gastrointestinal

FIG. 8.14 Radiograph of the jaws of a 4-year-old girl with suppurative osteomyelitis of the left mandible. The film shows marked destruction of the body and ramus of the mandible.

tract and high penetration of bone, but these drugs are generally considered second-line therapy options because of the potential of musculoskeletal adverse events in the pediatric population.⁵ As results from smears and culture are obtained, antibiotics may be changed unless the infection is responding favorably, in which case no change is made. The involved tooth is removed as early as possible to allow drainage and provide material for culture.

Antibiotic therapy is continued for at least 2 to 4 weeks after all symptoms subside. If the infection persists, repeated cultures are obtained, and the antibiotic is changed if necessary. The greater vascularity of the jaws may explain their more rapid response to antibiotic therapy and surgery in contrast to that of the long bones. The duration of intravenous antibiotic therapy in osteomyelitis of the jaws may not need to be as prolonged as in that of the long bones. Consideration should be given to sequestrectomy, saucerization, or the placement of closed-wound irrigation and suction. Saucerization involves the removal of teeth in the immediate area and removal of the overlying buccal plate of bone, allowing access to the medullary portion and sequestra that may be present. Placement of catheters through an extraoral approach occasionally is necessary for closed irrigation and suction. It permits instillation of antibiotics, allowing direct contact with the bone. Hyperbaric oxygen treatment may be considered in chronic cases refractory to antibiotic treatment.⁶⁶

Infantile Osteomyelitis

Osteomyelitis of the jaws in a newborn is an uncommon occurrence but warrants special mention because of its serious sequelae. It occurs most often a few weeks after birth and usually involves the maxilla. It is not odontogenic in origin but is thought to arise from neonatal trauma to oral tissues, hematogenous spread (from skin, middle ear, mastoid, or tonsils), or an infected nipple.⁸⁴ The patient has facial cellulitis centered around the orbit (Fig. 8.15). Irritability and malaise precede development of cellulitis and are followed by marked elevation in temperature, anorexia, and dehydration. Extraorally, inner canthal swelling, palpebral edema with closure of the eye, conjunctivitis, and proptosis may be seen, together with a purulent discharge from the nose or inner canthus. Oral examination shows swelling of the maxilla on the affected side extending to the buccal and the palatal regions, with fluctuation often present with multiple sinus tracts. *S. aureus* is the organism usually found.

Aggressive, prompt treatment must be undertaken to prevent permanent optic damage, neurologic complications, loss of tooth buds and bone, and extension to the dural sinuses. Intravenous penicillin and a penicillinase-resistant penicillin are given simultaneously with surgical drainage of all fluctuant areas, repeated Gram smears, and culture and sensitivity testing. Antibiotics are continued orally for 2 to 4 weeks after all signs of the infection have disappeared. If sequestra form, they should be removed conservatively. Tooth buds may be lost, and surviving teeth may be deformed or discolored after eruption.

Garré Sclerosing Osteomyelitis

Garré sclerosing osteomyelitis, also known as chronic nonsuppurative sclerosing osteomyelitis and proliferative osteomyelitis of Garré,¹⁰ is notable because of the similarity of some of its characteristics to those of other neoplasms. It is characterized by a localized, hard, nontender

FIG. 8.15 Characteristic clinical picture of a 3-week-old child with infantile osteomyelitis. (Courtesy Dr. M. Michael Cohen Sr.)

FIG. 8.16 Enlargement of the right side of the mandible in a 12-year-old patient with Garré sclerosing osteomyelitis. The swelling is hard and nontender.

swelling of the mandible (Fig. 8.16). Lymphadenopathy, hyperpyrexia, and leukocytosis are not present. Garré osteomyelitis is associated commonly with a carious tooth, usually the lower first molar (Fig. 8.17), and a history of a past toothache. It also may be associated with a recent dental extraction or an infected flap of tissue over an erupting tooth.⁵⁹ Radiographs are impressive, showing a focal area of well-calcified, smooth bone proliferation that often has a laminated or onion-peel appearance (Fig. 8.18).

Garré osteomyelitis is thought to be a response to a low-grade stimulus, such as a dental infection, that influences the potentially active periosteum of young individuals. Its appearance resembles that of infantile cortical hyperostosis (Caffey disease), osteosarcoma, and Ewing sarcoma, and it must be distinguished from these conditions.²⁴ Treatment consists of extraction or endodontic treatment of the involved tooth, with continued clinical and radiographic follow-up of the patient to ensure that the new bone formation does not progress. Ordinarily, remodeling occurs over the course of time, but biopsy should be done to rule out neoplasm if the lesion does not regress. No antibiotic therapy is necessary.

FIG. 8.17 Radiograph of a deeply carious lower first molar tooth with periapical spread of infection. It is the usual cause of Garré osteomyelitis.

HERPES SIMPLEX VIRUS INFECTIONS

HSV type 1 infections commonly are manifested as herpetic gingivostomatitis.⁹⁶ Five stages of infection have been identified: (1) primary mucocutaneous infection, (2) acute infection of ganglia, (3) establishment of latency, (4) reactivation, and (5) recurrent infection.

Primary infection is established by direct contact with individuals who have draining lesions or asymptomatic carriers who may continue to shed the virus despite the lack of symptoms. The highest incidence of primary infection appears to be in children 2 to 4 years old. Infants are protected by maternal antibodies, which may explain why this infection is not found in infants younger than 6 months. It appears to have no seasonal variation or male or female difference in incidence.

The incubation period is thought to be approximately 6 days, followed by the development of small vesicles that may coalesce to form larger lesions or ulcers. In severe cases, the lips, gingivae, oral mucosa, and pharynx may be involved. Many patients with primary herpes labialis may be asymptomatic, however, and symptoms may not develop. Healing occurs in 1 to 2 weeks, with gradual crusting of the lesions followed by re-epithelialization.

Latency is thought to continue throughout life, with reactivation occurring at various times, possibly triggered by actinic radiation and emotional or physical stress. Recurrent disease is manifested by vesicles at the mucocutaneous border, which are painful for about 2 days, followed by crusting and complete healing in 7 to 8 days.

Fifty percent of the adult population in industrialized countries and a higher percentage in less developed countries may have recurrent herpes labialis. Many, if not most, adults who have recurrent “cold sores” are not aware that they can transmit the disease and should be counseled in this regard. Likewise, medical, dental, and nursing personnel should be advised that occurrence of cutaneous lesions (herpetic whitlow) is possible after direct contact of the practitioner’s fingers with lesions during the physical examination.

In treating recurrent herpes labialis in nonimmunocompromised adults, acyclovir has been shown to decrease the duration of symptoms by 12 to 24 hours, at a cost of approximately \$75 per day. However, frequent use of acyclovir also may promote the spread of resistant viral strains. The use of acyclovir for treatment of recurrent herpes labialis in nonimmunocompromised individuals seems to offer little benefit at significant expense and risk.⁸³

INTRAORAL AND PERIORAL PIERCINGS

Tattoos and piercings are not uncommon in the adolescent population. Forty-six percent of teenagers will receive their first piercing between the ages of 11 and 16 years.¹⁶ The mouth and surrounding tissues are commonly pierced sites, with the tongue being the most frequently pierced.^{55,72} Moreover, a lack of awareness exists among these age groups on the risks associated with these body modification practices.⁷² Many times these piercings are performed by nonregulated piercing parlors and unlicensed personnel.¹¹⁰

Complications from piercing have ranged from simple local complications, such as bleeding, pain, and local infections, to severe, life-threatening infections.^{103,110} Among the most severe complications, bacterial endocarditis and brain abscess have been reported. Yu and associates,¹¹⁰ in a review on bacterial complications of oral piercings, found eight cases of bacterial endocarditis after oral piercings reported between 2001 and 2009, of which two were teenagers. Oral organisms such as *S. viridans*, *S. aureus*, and *Gemella* and *Neisseria* spp. were reported. Ludwig angina, glossal abscesses, and lymphadenitis, among other conditions, also were included in their report. Martinello and Cooney⁶³ reported a case of a solitary brain abscess in a patient 1 month after a tongue piercing. The abscess was polymicrobial with *S. viridans*, *Pep-tostreptococcus micros*, and *Actinomyces* and *Eikenella* spp. isolated.

Because of the risks associated with the use of oral jewelry and piercing, the AAPD has issued a statement strongly opposing the practice of piercing intraoral and perioral tissues and the use of jewelry on these tissues.²

Pharyngitis (Pharyngitis, Tonsillitis, Tonsillopharyngitis, and Nasopharyngitis)

James D. Cherry

Pharyngitis is an inflammatory illness of the mucous membranes and underlying structures of the throat. The clinical diagnostic category includes tonsillitis, tonsillopharyngitis, and nasopharyngitis; inflammation also frequently involves the uvula and soft palate. Illness usually is acute but also may be subacute or chronic. Establishing the diagnosis of pharyngitis requires objective evidence of inflammation (erythema, exudate, or ulceration). The symptom of sore throat invariably accompanies pharyngitis, but it should not be used as the sole criterion; sore throat is a

common complaint of children with colds in whom no objective evidence of pharyngeal inflammation is present (see Chapter 7).

Although the clinical finding of pharyngitis suggests an almost exclusive group A streptococcal cause to many physicians, etiologic considerations should include a multitude of viruses, bacteria, and other infectious and noninfectious agents. Etiologically, pharyngitis is subdivided into two categories: illness with nasal symptoms (nasopharyngitis) and illness without nasal involvement (pharyngitis or tonsillopharyngitis).

In acute illness, nasopharyngitis nearly always is of viral origin, whereas pharyngitis without nasal signs has diverse etiologic possibilities, including bacteria, viruses, fungi, and other unidentified causes. In this chapter, nasopharyngitis and pharyngitis without nasal involvement are considered separately.

HISTORY

Although throat inflammation undoubtedly has been a physical finding of disease throughout human existence, only in more recent years has attention been given to pharyngitis as a primary complaint. The throat findings of diphtheria were mentioned in the 3rd century AD,¹⁸⁹ and Vincent angina was noted in the military before the Christian era,⁵⁷ but group A streptococcal infection and pharyngitis were not clearly associated until World War II.^{37,158} Although Glover and Griffith⁷⁰ mentioned streptococcal tonsillitis in 1931, the major reference to streptococci in the preantibiotic era was in association with scarlet fever, erysipelas, and suppurative processes.²⁹

In the early years of clinical virology large population studies of colds, pharyngitis, croup, bronchiolitis, and pneumonia were carried out.* In more recent years, studies have been mainly related to new agents, and pharyngitis is an illness category that is frequently overlooked.

NASOPHARYNGITIS

Etiologic Agents

Etiologic agents of nasopharyngitis, categorized by type of lesion, frequency, season of occurrence, and duration of illness, are listed in Table 9.1. The relative importance of nasal and pharyngeal manifestations also is presented. Although Table 9.1 shows three bacterial agents and one rickettsia, most occurrences of nasopharyngitis are caused by viral infections. The specific infectious agents are discussed fully in their respective sections of this book; only an overview is presented here.

Adenoviruses are the most common cause of nasopharyngitis; types 1, 2, 3, 4, 5, 6, 7, 7a, 9, 14, and 15 account for most illnesses.^{14,27,40,41,95,131,148,173,179,194} Nasopharyngitis also commonly occurs with influenza and parainfluenza viral infections.[†] Although rhinoviral, respiratory syncytial viral, human metapneumovirus, and human bocavirus infections are common occurrences in children and all always have nasal manifestations (coryza), the occurrence of objective pharyngeal manifestations is less common.[‡]

Respiratory symptoms with cough, nasal discharge, and pharyngitis frequently occur in children with rotaviral gastroenteritis.^{77,112,159}

Epidemiology

Nasopharyngitis is a common illness of childhood. It tends to be most prevalent in young children in association with primary infections with respiratory viruses. Nasal symptoms with enteroviruses occur less frequently in school-aged children than in preschool-aged children. In contrast, older children rarely have pharyngitis with respiratory syncytial viral, parainfluenza viral, and rhinoviral infections. Nasopharyngitis caused by adenoviral infection is a particularly frequent occurrence in adolescents and young adults in military training.^{40,173,194}

Nasopharyngitis occurs more commonly during the cold-weather months (see Table 9.1). No apparent sex predilection has been found. The method of transmission is similar to that of other respiratory viral infections (see Chapter 7).

Pathophysiology

The pathophysiology of nasopharyngitis is discussed in Chapter 7, in the pharyngitis section of this chapter, and in the chapters discussing the individual viral agents. In nasopharyngitis associated with *Haemophilus influenzae* and *Neisseria meningitidis*, the nasal symptoms may result from a concomitant respiratory viral infection.²⁹

Clinical Presentation

Because nasopharyngitis is caused by many different etiologic agents, a reasonable expectation is varied clinical manifestations. These differences are highlighted in Table 9.1. Fever occurs in nearly all cases of nasopharyngitis. With adenoviral and influenza viral disease, the pharyngeal findings are most prominent; with the other respiratory viruses, coryza is more notable than are pharyngeal complaints. In adenoviral infections, follicular pharyngitis is the rule, and exudate is a common manifestation. In contrast, patients with the other respiratory viral infections usually present with pharyngeal erythema only. Nasopharyngitis of a viral etiology most often is an acute, self-limited disease lasting 4 to 10 days. Generally, adenoviral illnesses tend to be more prolonged than are illnesses resulting from the other respiratory viruses. Other symptoms in nasopharyngitis are related to the causative virus. Parainfluenza and respiratory syncytial viral infections also frequently have lower respiratory tract findings (laryngotracheitis, pneumonia, or bronchiolitis), and influenza is usually associated with more severe, generalized complaints.

Although respiratory symptoms in association with rotaviral gastroenteritis have been noted frequently, little careful clinical study of the respiratory manifestations has been performed. Lewis and associates,¹¹² in a careful study observed a statistically significant occurrence of nasal discharge, cough, and red throat in children with rotaviral diarrhea compared with children with diarrhea caused by other agents.

Nasopharyngitis with *H. influenzae* or *N. meningitidis* infections has been noted mainly in patients with septicemia and meningitis. The nasal symptoms (coryza) usually preceded the pharyngitis and severe systemic disease by a few to several days. In Q fever, the predominant finding is pneumonia. With diphtheria, the exudative pharyngitis and constitutional symptoms are most prominent.

PHARYNGITIS, TONSILLITIS, AND TONSILLOPHARYNGITIS

Etiologic Agents

Etiologic agents of pharyngitis categorized by type of lesion, frequency of occurrence, and duration of illness are presented in Table 9.2. Numerous diverse possibilities exist for the differential diagnosis of pharyngitis. The specific agents or factors are presented in their respective sections of this book, and only an overview is given here.

As with all infectious diseases, etiologic prevalence depends on multiple factors (status of the host, age, season, environment, exposure, and type of lesion) that must be considered in each individual case. In otherwise healthy children, the following infectious agents account for more than 90% of acute infections with pharyngeal involvement: *Streptococcus pyogenes*; adenoviruses; influenza viruses A and B; parainfluenza viruses 1, 2, and 3; Epstein-Barr virus; enteroviruses; and *Mycoplasma pneumoniae*.^{*} Although group A streptococci are suggested frequently²⁹ as the only worthy bacterial consideration in the etiology of pharyngitis, the data in Table 9.2 indicate broader possibilities. When streptococci with β -hemolysis recovered from children and adolescents with pharyngitis are typed, group B, C, and G strains occasionally are found.^{9,32,34,68,84,190,191} Turner and associates¹⁹⁰ found that of the group C streptococci, only *Streptococcus equisimilis* caused pharyngitis; *S. anginosus* (formerly *S. milleri*) was part of the normal oropharyngeal flora.

Laboratory accidents have provided evidence that *H. influenzae* can cause pharyngitis,^{143,197} and children with systemic illnesses caused by *H. influenzae* and *N. meningitidis* frequently have an associated marked pharyngitis.^{172,198,203} *Arcanobacterium haemolyticum* and *Corynebacterium ulcerans* occasionally cause an illness mimicking diphtheria.^{21,76,98,103,121,149} *A. haemolyticum* also causes an illness that has been confused with streptococcal scarlet fever.^{55,98,117,121}

Because anaerobic microorganisms are universal constituents of the normal throat flora, assigning etiologic significance to these agents in

HIV, Human immunodeficiency virus; *PFAPA*, periodic fever, aphthous stomatitis, pharyngitis, and adenitis (syndrome).

throat infections frequently is difficult. Vincent stomatitis and angina seem to result from mixed infections with anaerobes.^{58,71,120,193} Brook and Gober¹⁷ noted a significant association between encapsulated organisms of the *Bacteroides melaninogenicus* group (*Prevotella melaninogenica*) and acute tonsillitis in children. My impression is that acute and subacute infections with anaerobes account for numerous pharyngeal infections in adolescents in which cultures do not reveal group A streptococci and infectious mononucleosis test results are negative. Gonococcal and treponemal infections should be considered in sexually active or known exposed teenagers and other children.^{23,38,59,92,202}

Adenoviral types 1, 2, 3, 4, 5, 6, 7, 7a, 9, 11, 14, 15, and 16 are the most common causes of pharyngitis in young children, and they are prominent etiologic agents in older children and adolescents.^{14,24,40,42,131,134,148,173,179,194} Pharyngeal involvement frequently is overshadowed by other respiratory symptoms (e.g., cough, coryza) in parainfluenza viral infections and by systemic complaints (e.g., fever, exanthem, meningitis) in enteroviral infections.* An enteroviral etiology should be suspected when small ulcerative lesions are noted that involve the soft palate and uvula and the posterior pharyngeal wall (see Chapter 166). Infection with Epstein-Barr virus causes infectious mononucleosis with pharyngeal involvement similar to that resulting from group A streptococcal infection.^{85,195} The clinical manifestations of Epstein-Barr virus are age-related; young children rarely have marked pharyngeal involvement.

Acquired cytomegalovirus infection causes an infectious mononucleosis-like syndrome, but pharyngitis occurs less commonly than it does in Epstein-Barr virus mononucleosis.¹⁰⁵ Primary and recurrent herpes simplex virus (HSV) infections occasionally have pharyngeal manifestations.^{25,29,51,131} Many illnesses that are ascribed clinically to HSV actually are misidentified instances of aphthous stomatitis, however. Virtually all instances of HSV infections with pharyngitis also reveal lesions in the anterior mouth and externally around the mouth. Although Koplik spots are known universally as the enanthem of measles, many physicians are unaware of the diffuse nature of the associated measles pharyngitis.²⁸ Primary infection with human immunodeficiency virus may cause the acute retroviral syndrome with fever, nonexudative pharyngitis, lymphadenopathy, exanthem, arthralgia, myalgia, and lethargy.¹⁰

The role of *Chlamydia* in the cause of pharyngitis is unclear. Grayston and associates^{75,74} noted the occurrence of pharyngitis in adolescents and young adults infected with *Chlamydia pneumoniae* (formerly *Chlamydia pneumoniae*). In a study in children, IgM antibody to *Chlamydia trachomatis* was found in children with pharyngitis.⁸⁰ Because cross-reactivity between *C. trachomatis* and *C. pneumoniae* exists, the illnesses studied were likely to be caused by *C. pneumoniae* rather than by *C. trachomatis*. Ogawa and colleagues¹³⁸ noted prolonged and recurrent tonsillitis in association with sexually transmitted *C. trachomatis*.

Mild pharyngitis occurs in young children with *M. pneumoniae* infections; in older children, pharyngeal involvement is more pronounced.^{31,69,73,89} In young adult volunteers, *Mycoplasma hominis* was noted to cause pharyngitis.¹¹⁶ Although lower respiratory tract findings and systemic complaints are most marked in Q fever, moderate subjective and mild objective evidence of pharyngitis also is noted.^{48,94,141} Exudative pharyngeal involvement with *Candida* spp. commonly occurs.^{110,174} *Candida* infection most commonly occurs in children whose normal throat flora has been disrupted and in children who have a compromised immunologic response.

Recurrent aphthous stomatitis usually involves the anterior oral cavity but occasionally is noted with extensive pharyngeal and soft palate lesions.^{72,110,160,174} Although L-forms (spheroplasts) of *Streptococcus sanguinis* can be recovered consistently from the lesions of this disease,^{72,110,160,174} their role in the etiology is unclear.

In Behçet syndrome, the ulcerative lesions are subacute or chronic and usually are not associated with surrounding pharyngeal inflammation.¹²³ In Kawasaki disease, the pharyngeal mucosa is deeply erythematous.¹²⁹

Pharyngeal involvement is a common occurrence in noninfectious illnesses in which host resistance has been altered. The lesions usually

are ulcerative, but secondary bacterial or fungal overgrowth can lead to marked erythematous and exudative findings.

Epidemiology

Pharyngitis is a common occurrence in children and, as noted in Table 9.2, is the result of many different infectious agents. Generally, bacterial pharyngitis occurs more commonly in the cold-weather seasons; an enteroviral etiology is most common in the summer and fall. In younger children, viral pharyngitis tends to occur more frequently than does bacterial disease.⁴² It has no apparent sex predilection.

Most diseases associated with pharyngitis require close person-to-person contact for spread. Pathogens are transmitted directly by close-range airborne dissemination or indirectly by the hands of the future host. Several food-borne outbreaks of streptococcal pharyngitis have been reported.^{52,62} Prechewing of food by adults also may be a cause of streptococcal pharyngitis in infants.¹⁷⁸

Pathophysiology

The pathology and pathophysiology of diseases in which pharyngitis is prominent are presented in the chapters of this book on specific infectious agents (in particular, see Chapters 82, 156, 160, 166, and 196).

Clinical Presentation

General

The clinical findings in pharyngitis are highlighted in Table 9.2. Manifestations related to individual pathogens are detailed in the chapters of this book dealing with the specific agents. The onset of pharyngitis usually is sudden and accompanied by fever and the complaint of sore throat. Frequently, parents observe that the child's breath is not normal and that the throat and particularly the tonsils are red. Other initial complaints include headache, nausea, vomiting, and sometimes abdominal pain. Anorexia is the rule, as is some degree of lessened activity. Parents also report frequently that the child's cervical lymph nodes are enlarged and tender.

Physical examination usually substantiates the parents' observations—the child is febrile with moderate to severe pharyngeal erythema and some degree of cervical adenitis. As noted in Table 9.2, the pharyngeal response varies. With acute common infections, the basic lesion is erythema. Associated with erythema can be follicular, ulcerative, and petechial lesions and generalized or circumscribed exudative areas. Follicular lesions are most characteristic of adenoviral infections, whereas exudative lesions occur most commonly in group A streptococcal infections and in infectious mononucleosis. Meland and associates¹²⁸ noted that the absence of cough and the presence of swollen lymph nodes had the highest specificity in predicting a streptococcal cause of pharyngitis. Ulcerative lesions are observed most frequently in enteroviral infections (see Chapter 166). Petechiae on the soft palate frequently are seen in group A streptococcal infections but also commonly occur in infectious mononucleosis, measles, and rubella.

Occurrences of pharyngitis in children almost always are acute, self-limited diseases. Pharyngitis of viral origin lasts 4 to 10 days, and pharyngitis caused by group A streptococci, if untreated, lasts slightly longer. Subacute and chronic pharyngeal disease is an uncommon occurrence in children, but the etiologic possibilities are numerous (see Table 9.2).

PERIODIC FEVER, APHTHOUS STOMATITIS, PHARYNGITIS, AND ADENITIS

In 1987, Marshall and colleagues¹²⁵ described a new syndrome, periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA), and it subsequently has been reported on by many others.* In 1999, Thomas and associates¹⁸⁷ presented an analysis of data in their PFAPA registry of 94 cases. The male-to-female ratio was 1.8:1, and the mean age of PFAPA onset was 2.8 years (95% confidence interval [CI], 2.4–3.3). The children had an average 11.5 febrile episodes per year, and the average symptom-free interval between episodes was 28.2 days (99%

*References 2, 11, 30, 39, 79, 88, 89, 96, 100, 131, 137, 144, 146, 156, 164, 170, 177, 184, 199.

*References 1, 18, 20, 53, 54, 63, 65, 87, 91, 93, 114, 118, 140, 182, 187, 205.

CI, 26–30.4 days). The average duration of an episode was 4.8 days, with the temperature being greater than 38.3°C (101°F) for 3.8 days. The average maximum temperature per episode was 40.5°C (104.9°F) (95% CI, 40.4–40.6°C [104.7–105°F]). Along with the periodic fevers, the children also experienced aphthous stomatitis (67%), pharyngitis (65%), cervical lymphadenopathy (77%), chills (80%), headache (65%), abdominal pain (45%), nausea (52%), diarrhea (30%), cough (20%), coryza (18%), and rash (15%). In addition to fever, 97% had one or more of aphthous stomatitis, pharyngitis, or adenopathy. The mean leukocyte count was 13,000 with 62% polymorphonuclear leukocytes, and the mean erythrocyte sedimentation rate was 41 mm/h.

Feder and Salazar⁵⁴ reported their review of 105 patients that they saw between 1998 and 2007. In this group there were 62% males. The median age at onset was 30 months (range, 3 to 144 months), the mean duration of febrile episodes was 4.1 days (range, 2 to 7 days), and the mean interval between episodes was 29.8 days (range, 14 to 50 days). It should be noted that, with any single episode of recurring fever, the patients often do not have all three of the syndrome manifestations (i.e., aphthous stomatitis, pharyngitis, and cervical adenitis).

In the Feder and Salazar⁵⁶ series the maximum temperatures ranged from 39.2°C (102.5°F) to 42.1°C (107.8°F), and other symptoms included headache, 44%; vomiting, 27%; and mild abdominal pain, 41%. The patients were said to be listless but not toxic. The parents of 46% of the children reported that their children with PFAPA were less likely to get respiratory and gastrointestinal viral illnesses that were circulating in their families and communities. Sixty-two percent of the children had a prodrome (fatigue, headache, abdominal pain, or irritability) that began 20 hours (mean) before the onset of fever. Patients in this series had normal white blood cell counts and erythrocyte sedimentation rates when afebrile. With illness the white blood cell count tended to be slightly elevated, with a preponderance of neutrophils. At the onset of illness, the C-reactive protein value was elevated.

Hofer and colleagues⁸⁷ analyzed 301 PFAPA cases in 15 centers in Europe. Of the 301 cases, 449 had the complete cluster of symptoms (pharyngitis, cervical adenitis, and oral aphthosis) with their episodes. Seventy-six percent of the patients had additional symptoms (131 gastrointestinal symptoms, 86 arthralgias and/or myalgias, 36 skin rashes, and 8 neurologic symptoms). There were 161 boys and 140 girls, the median age of onset was 1.7 years, the median interval between attacks was 4 weeks, and the median duration was 4 days.

Cochard and colleagues³⁶ studied the familial relationships in PFAPA syndrome. They noted a positive family history for recurrent fever in 38 of 84 (45%) children with PFAPA. The affected family member was a sibling or parent in 29 of 38 (76%) of the cases.

The etiology of the PFAPA syndrome is unknown. In extensive studies by Stojanov and associates,¹⁸² the following were noted in PFAPA attacks: complement (C1QB, C2, SERPIN G1), interleukin-1 (IL)-related (IL-1B, IL-1RN, CASP1, IL18RAP), and interferon-induced (AIM2, IP-10/CXCL 10) genes were overexpressed, and T-cell-associated transcripts (CD3, CD8B) were downregulated. During attacks, there were increased serum levels of chemokines for activated T cells (IP-10/CXCL 10, MIG/CXCL 9), granulocyte colony-stimulating factor, and proinflammatory cytokines (IL-18, IL-6). A relative lymphopenia was noted.

In another study, Brown and colleagues¹⁸ noted increased monocytes and decreased eosinophils during attacks and increased thrombocytes during the afebrile period. Kolly and coworkers¹⁰¹ noted that IL-1β monocyte production was dysregulated in patients with PFAPA syndrome.

Wurster and associates²⁰⁵ carried out a long-term follow-up study of 59 patients in a PFAPA registry. The follow-up time ranged between 12 and 21 years. Of this group 50 (85%) had complete resolution. The mean duration of the syndrome was 6.3 years (95% CI, 5.4–7.3) and none of these patients had sequelae.

Differential Diagnosis

As noted in Table 9.2, the differential diagnoses in pharyngitis are numerous, as in nasopharyngitis (see Table 9.1). Although considerable overlap exists in the spectrum of illness in pharyngeal infections, many clues help in ruling in or out certain diagnostic possibilities. The diagnosis of pharyngitis requires carefully eliciting epidemiologic and other historical data (i.e.,

exposure, season, incubation period, age of patient, associated clinical findings), in addition to observing pharyngeal physical findings.

Most acute instances of nasopharyngitis are of viral origin (see Table 9.1), with adenoviruses accounting for the greatest number of cases. Nasopharyngitis also occurs during epidemic influenza A and B and parainfluenza 1 and 2 infections and with sporadic parainfluenza 3 infections. In all cases, proper epidemiologic and historical data should be elicited so that early diphtheria and other unusual but treatable illnesses are not diagnosed incorrectly. Retrospective study has indicated that nasopharyngitis occasionally occurs in severe infections from *H. influenzae* and meningococci, so the possible presence of these infections should be considered when the epidemiology suggests it.

Although most cases of pharyngitis without nasal symptoms are caused by viral infections, numerous other etiologic possibilities exist. The approach taken frequently by many physicians is to consider all pharyngitis as being of bacterial origin and to treat it with antibiotics. The initial consideration in a child with pharyngitis should be the duration of illness. Subacute, chronic, and recurrent illnesses (see Table 9.2) generally suggest more unusual problems and require a more deliberate approach. In all instances of acute pharyngitis, ruling out streptococcal disease is mandatory.

PFAPA syndrome must be differentiated from *monogenic periodic fevers*, which are caused by mutations of genes involved in regulation of the inflammatory response.⁶⁵ These illnesses include familial Mediterranean fever, tumor necrosis factor receptor–associated periodic syndrome, and mevalonate kinase deficiency.

Specific Diagnosis

The epidemiologic history and careful clinical categorization are the most important aspects of specific diagnosis. The most pressing diagnostic need in upper respiratory tract infections in everyday pediatric practice is distinguishing bacterial from viral disease—who and who not to treat with antibiotics.

A child with the common cold, herpangina, or pharyngoconjunctival fever has a viral disease and does not need therapy with antibiotics. In most instances, when these clinical diagnoses are apparent, performing throat cultures for bacterial pathogens is unnecessary. A child with severe acute pharyngitis with exudate and fever and cervical lymphadenitis also is treated easily because most of these children have disease resulting from group A streptococci.

Because young children usually cry when examined by the physician, the clinical differentiation between pharyngitis/tonsillitis without nasal symptoms and nasopharyngitis is difficult. Therefore, on clinical grounds, there is no certain way to make an etiologic diagnosis and specifically to rule out infection caused by *S. pyogenes*. In the past, the usually recommended approach to management of pharyngitis and nasopharyngitis was to obtain a throat culture to determine whether group A streptococci were present. Because several rapid tests (RADTs) for the detection of group A streptococci are available, establishing the immediate diagnosis and providing treatment of streptococcal pharyngitis is recommended in the practice setting.*

Generally these rapid tests have high specificity, but sensitivity may be suboptimal. Today, a reasonable approach to establishing the diagnosis of streptococcal pharyngitis is to do an RADT. If the test result is positive, specific therapy is instituted. In the case of a negative rapid test result in children, a routine throat culture is done, and therapy is withheld pending the culture results.⁴⁶

A common approach is to obtain two throat swabs at the time the child is examined and send both to the laboratory. The laboratory can then run the RADT and only carry out the culture if the rapid test is negative for group A streptococci.

A question exists regarding whether early treatment of streptococcal pharyngitis is desirable.^{47,66,67,151,152} In the public clinic, where following up children with positive throat cultures often is difficult, providing immediate diagnosis and treatment is important. As Pichichero and associates¹⁵⁷ and El-Daher and colleagues⁴⁷ have shown, early treatment may result in a decreased desirable antibody response, allowing reinfection with type-specific organisms to occur. In settings in which the

*References 45, 46, 56, 104, 108, 122, 152, 154, 169, 175, 180, 186, 201.

communication between physicians and parents is satisfactory, a reasonable approach in many instances is to withhold the institution of treatment for 1 or 2 days. Gerber and associates^{47,66,67} argued against this approach because providing immediate therapy can reduce the risk of transmission of infection, and they challenged the interpretation of the findings of Pichichero and associates¹⁵² and El-Daher and colleagues.⁴⁷

Cultures for other pathogens should be reserved for unusual situations, such as persistent symptoms, indicative epidemiology, or other pertinent historical data. Because *H. influenzae* and *Streptococcus pneumoniae* frequently are part of the normal flora, their isolation is not always etiologically significant. If cultures reveal predominant growths of either *H. influenzae* or *S. pneumoniae*, however, they are likely contributing to the disease process, and antibiotic therapy directed at the specific pathogen would benefit the patient.^{29,124,203} When the possibility of disease because of anaerobic agents exists, a gram-stained smear from an exudative area may be rewarding. When the pharyngeal findings are unique, or when many cases of a similar illness are observed, a viral culture or direct antigen test from the throat is indicated.

Treatment

The specific treatments of diseases with nasopharyngitis and pharyngitis are discussed in chapters of this book that deal with the individual pathogens. That antimicrobial agents are prescribed inappropriately in children with sore throat and pharyngitis is common knowledge. Based on the etiologic agents noted in Tables 9.1 and 9.2, it is apparent that many infectious agents that are associated with nasopharyngitis and pharyngitis can be treated effectively with antimicrobial agents. However, except in rare specific circumstances, the only common pathogen that requires treatment is the group A streptococcus. The treatment of streptococcal pharyngitis is discussed in detail in Chapter 82.

Although a multitude of proprietary remedies are available for respiratory tract infections, and sore throat specifically, none has a place in the care of pediatric patients. Particularly to be condemned are throat lozenges that contain numerous useless ingredients, many potentially harmful. Antibiotic-containing lozenges particularly are to be condemned because they may allow streptococcal disease to go unrecognized. Antiseptic mouthwashes have no value, and decongestants and antihistamines have no proven efficacy and frequently lead to troublesome side effects.

Corticosteroids have been used for pain relief in acute pharyngitis, and although they appear to be modestly effective, I believe that this is a bad practice that should be discouraged.^{82,102,206,163,166}

Because children with pharyngitis frequently feel ill, therapy with an analgesic is reasonable. Formerly, aspirin was the analgesic usually recommended. However, because aspirin is an etiologic factor in influenza-associated Reye syndrome and because differentiating influenza viral infections from other respiratory viral infections is difficult clinically, using acetaminophen rather than aspirin is prudent. The dose per single administration of acetaminophen by year of age is as follows: younger than 1 year, 60 mg; 1 to 3 years, 60 to 120 mg; 3 to 6 years, 120 mg; 6 to 12 years, 150 to 300 mg; older than 12 years, 325 to 650 mg. Administration may be repeated three or four times daily in young children and every 4 hours in older children. Acetaminophen rarely should be given to infants younger than 6 months old. In young children, careful attention to adequate hydration is particularly necessary.

Children with PFAPA syndrome have been treated with corticosteroids, cimetidine, tonsillectomy, and colchicine.^{19,54,64,82,87,102,113,125,187,206} Most often used is prednisolone 1 mg/kg in a single dose.⁵⁶ Some patients received one or two additional doses at 12-hour intervals. This treatment is highly effective in reducing the duration of the febrile episode. However, this treatment tends to shorten the interval between febrile episodes by 7 to 14 days. Feder and Salazar⁵⁴ note that in their experience with prednisolone treatment the initially shortened cycles lengthened over time. Burton and associates¹⁹ review two randomized tonsillectomy trials. It was noted that tonsillectomy resulted in a reduction in the frequency and severity (length of episodes) of future experiences.

Stagi and associates¹⁷⁶ studied 25 Italian patients and found that these children had low vitamin D serum levels. Vitamin D supplementation in these children reduced the frequency and severity of PFAPA flares.

Complications

The main bacterial complications associated with tonsillitis/pharyngitis are retropharyngeal and peritonsillar abscesses and Lemierre syndrome (see Chapter 11). Nonbacterial complications include rheumatic fever, acute glomerulonephritis, and pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (see Chapters 29 and 82).

Prognosis

Almost all occurrences of nasopharyngitis and pharyngitis are self-limited, and the overall prognosis is excellent. Keeping a constant vigil for streptococcal and other more serious diseases is necessary, however. Failure to diagnose and treat group A streptococcal infections, syphilis, and other more unusual infections can lead to serious short- and long-term difficulties.

Prevention

Because pharyngitis and nasopharyngitis are caused by infections with many different respiratory pathogens, no practical specific approach to prevention exists. Occasionally, streptococcal disease can be prevented by the judicious use of prophylactic penicillin. For young children or others with undue susceptibility to serious disease with common respiratory pathogens, reducing contact situations (e.g., daycare centers) is prudent. In the 1980s, Paradise and colleagues¹⁴² studied the effect of tonsillectomy on the rate of recurrent throat infections in severely affected children. In this controlled study, children needed to have a history of seven or more episodes of tonsillitis in the preceding year, or five or more episodes in each of 2 preceding years, or three or more episodes in the 3 preceding years. The findings in this study indicated that children in the surgical group had significantly fewer throat infections than occurred in the nonsurgical control group during the ensuing 2 years of follow-up. In a more recent but similar study with less stringent criteria for surgery, Paradise and colleagues¹⁴⁷ found that tonsillectomy or adenotonsillectomy conferred a modest benefit. They concluded, however, that the modest benefit of tonsillectomy or adenotonsillectomy in children with recurrent throat infections does not justify the risks, morbidity, and cost of the operations.

Blakley and Magit¹² reviewed four randomized controlled trials in which tonsillectomy was favored over medical therapy in reducing pharyngitis and found in only one of these trials that the result was statistically significant. Their meta-analysis suggested that tonsillectomy resulted in a 43% reduction in the incidence of pharyngitis.

Infections of the uvula have been reported infrequently in the medical literature. When the uvula is the most inflamed structure in the posterior pharynx of a febrile child, acute infection should be suspected. Other causes of uvulitis include trauma (from instrumentation), ischemia due to pressure from an endotracheal tube or laryngeal mask airway, inhalant irritation (from use of recreational drugs, including cocaine, cannabis, and mephedrone), vasculitis, and allergy.^{1,3-5,9,13,14,18}

ETIOLOGY

The main bacterial agents that cause uvulitis in children include *Haemophilus influenzae* type b and *Streptococcus pyogenes*.⁸ Uvulitis caused by *H. influenzae* may occur concurrently with epiglottitis or as an isolated infection.^{10,17} Uvulitis caused by *S. pyogenes* seems always to occur in concert with pharyngitis. Brook² reported two cases of uvulitis caused by anaerobic bacteria (*Fusobacterium nucleatum* and *Prevotella intermedia*). No search for viral agents has been conducted. Several cases of uvulitis caused by *Candida albicans* have been described in immunocompetent toddlers.⁹ In adults, *Streptococcus pneumoniae* and *H. influenzae* have been reported to cause uvulitis.^{6,16} In many patients, an associated epiglottitis has been present.^{12,16}

EPIDEMIOLOGY

The epidemiology of uvulitis is the epidemiology of its two etiologic agents, *S. pyogenes* and *H. influenzae* type b. It occurs in school-aged children 5 to 15 years old (the so-called streptococcal age group) in association with pharyngitis. Similarly, it can be seen in the *H. influenzae* age group (3 months to 5 years) if a child has not received the now routine and universally recommended conjugate vaccine to prevent infections caused by *H. influenzae* type b. Cases of uvulitis in association with epiglottitis have been reported in the United States and in England.^{2,8,15} Infections caused by *S. pyogenes* and *H. influenzae* occur primarily in the winter and spring, but both types can occur throughout the year.

PATHOGENESIS

Uvulitis is an acute cellulitis characterized by dramatic swelling and erythema. Infection of the uvula probably arises from direct invasion by *S. pyogenes* or *H. influenzae* type b; both are recognized as normal nasopharyngeal flora. In the latter case, epiglottitis also may arise by direct extension, and the bacteremia may result secondarily from either the uvula or the epiglottitis as a primary site of infection.

Uvulitis that is noninfectious may result from injury, chemical irritation, or allergic inflammation. An occurrence in a child who was ultimately diagnosed to have Kawasaki disease also has been reported.⁷

CLINICAL MANIFESTATIONS

In a review of five patients with streptococcal uvulitis, all had associated pharyngitis.⁸ The patients presented with low-grade fever and sore throat. Three of the five patients experienced a choking or gagging sensation in the pharynx that induced coughing and spitting; one of these patients also presented with drooling. Although pharyngitis was noted on physical examination, the swelling and erythema of the uvula were most dramatic (Fig. 10.1). None of the patients had evidence of respiratory distress.

In most children with uvulitis and epiglottitis, the presentation usually is typical for epiglottitis, with sudden onset of high fever, dysphagia, and increasing respiratory distress. Rapkin,¹⁵ however, reported a case of uvulitis and epiglottitis in a child in which the epiglottitis initially was unsuspected. The same observation has been made in some adults with uvulitis and epiglottitis.^{6,12} Lateral neck radiography (performed in one case to evaluate the possibility of a retropharyngeal abscess) belatedly alerted the clinicians to the correct diagnosis.

In patients with uvulitis and no epiglottitis, the presentation may be similar to that of epiglottitis, with acute onset of fever, odynophagia, and drooling, or, less specific, with fever and irritability or decreased appetite.^{10,11,17} The diagnosis in these cases is provided by physical examination of the oropharynx, which shows a swollen and erythematous uvula (see Fig. 10.1).

DIAGNOSIS

The diagnosis of streptococcal uvulitis is suspected when a school-aged child presents with low-grade fever, pharyngitis, and uvulitis. The diagnosis is confirmed by the recovery of *S. pyogenes* from a surface culture of the throat or uvula or both.

The diagnosis of uvulitis caused by *H. influenzae* is suspected in a highly febrile infant or preschool-aged child who has uvular inflammation on physical examination. Lateral neck radiography must be performed to evaluate the possibility of epiglottitis unless obvious signs of upper respiratory tract obstruction are present, in which case immediate endoscopy is warranted. If epiglottitis is discovered, the airway must be secured, and appropriate parenteral antimicrobial agents must be initiated after blood and surface culture specimens are obtained. Any surface culture specimen obtained to search for *H. influenzae* must be plated onto chocolate agar. After appropriate culture specimens are obtained, parenteral antimicrobial agents should be initiated, as in other infections associated with bacteremia caused by *H. influenzae*.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with acute onset of fever, dysphagia, and drooling includes herpes simplex gingivostomatitis, uvulitis, epiglottitis, severe pharyngitis, and peritonsillar or retropharyngeal abscess. Although being extremely cautious in examining the pharynx of any patient with suspected epiglottitis is appropriate, some children tolerate attempted visualization of the oral cavity without becoming unduly upset. Instrumentation with a tongue blade should be avoided. If the examination does not show gingivostomatitis or peritonsillar abscess, lateral neck radiography should be performed. If epiglottitis or retropharyngeal abscess is confirmed, management of the airway and administration of antimicrobial agents are indicated for epiglottitis, and incision and drainage and administration of antimicrobial agents are indicated for retropharyngeal abscess. If the lateral neck is normal and the uvula is inflamed, uvulitis with or without pharyngitis is confirmed.

TREATMENT

Management of uvulitis is guided primarily by the associated pharyngitis or epiglottitis, if either is present. In the case of streptococcal pharyngitis, penicillin therapy for 10 days is most appropriate. These patients usually can be treated orally with penicillin V 25 to 50 mg/kg per day administered in two divided doses.

FIG. 10.1 Swollen (two to three times normal size) and erythematous uvula in a patient without epiglottitis or pharyngitis.

In the case of uvulitis and epiglottitis, management of the airway is most important and can be accomplished by performing nasotracheal intubation or tracheotomy. Appropriate parenteral antibiotic therapy usually is initiated.

In the case of uvulitis without epiglottitis in an infant or preschool-aged child, antimicrobial therapy should be planned for possible *H.*

influenzae type b bacteremia. As many as 50% of respiratory isolates of *H. influenzae* produce β -lactamase. Administration of an advanced-generation cephalosporin, such as cefotaxime 200 mg/kg per day in four divided doses or ceftriaxone 100 mg/kg per day in one dose or two divided doses, is appropriate. In a patient with serious penicillin hypersensitivity, aztreonam 100 mg/kg per day in three divided doses and ciprofloxacin 30 mg/kg per day in two divided doses are also satisfactory regimens. After the patient has defervesced and has improved clinically, an oral antimicrobial agent can be substituted. The results of blood and surface cultures now can guide therapy. For an ampicillin-susceptible *H. influenzae* infection, amoxicillin 45 mg/kg per day in two divided doses should be prescribed to complete a 7- to 10-day course of treatment. For β -lactamase-producing *H. influenzae*, a variety of oral agents, including cefixime 10 mg/kg in a single daily dose, cefuroxime 30 mg/kg per day in two divided doses, or amoxicillin-potassium clavulanate (45 mg/kg per day of amoxicillin) in two divided doses, can be prescribed.

Resolution was prompt in the two cases of uvulitis allegedly caused by *C. albicans*. One child was treated with topical nystatin, and the other had spontaneous improvement.⁹

Peritonsillar, Retropharyngeal, and Parapharyngeal Abscesses

11

Nira A. Goldstein • Margaret R. Hammerschlag

A deep neck abscess is a collection of pus in a potential space bounded by fascia.⁸ These potential spaces are areas of least resistance to the spread of infection. An infection may begin with a minimal area of cellulitis and progress to a deep neck abscess, which may extend to invade adjacent potential spaces; these spaces frequently encompass vital structures in the neck. Destruction and dysfunction of these structures represent the major complications of deep neck infections.⁶³

EPIDEMIOLOGY OF HEAD AND NECK SPACE INFECTIONS IN CHILDREN

Head and neck space infections in children are not uncommon. A survey of members of the American Academy of Otolaryngology found the incidence of peritonsillar abscesses to be approximately 30 per 100,000 person-years, or approximately 45,000 cases annually in the United States and Puerto Rico,⁴⁷ whereas a 3-year study in Sweden in a well-defined catchment area of 179,200 inhabitants reported an incidence of 37 per 100,000 person-years.⁸⁵ Data from the 2009 Kids' Inpatient Database (KID) that included data from 2 to 3 million pediatric hospitalizations occurring in 44 states reported an incidence of 9.4 peritonsillar abscesses per 100,000 person-years, 2.2 retropharyngeal abscesses per 100,000 person-years, and 2.0 parapharyngeal abscesses per 100,000 person-years.⁸⁰ There was a statistically significant increase in the incidence of retropharyngeal abscesses from 2000 to 2009 (1.0 to 2.2 cases per 100,000 person-years) but there was no change in the incidence of peritonsillar (8.2 to 9.4 cases per 100,000) or parapharyngeal (0.8 to 1.4 cases per 100,000) abscesses. Elsherif and associates³⁴ described 130 cases of retropharyngeal abscess between 2002 and 2007, and the incidence significantly increased over the study period from 13 cases

in 2002 to 44 in 2007. Wright and colleagues¹¹² also found a doubling in the number of cases of retropharyngeal space infections from 1997 to 2001 versus 2001 to 2005. In contrast, Segal and associates⁹³ found no increase in the number of peritonsillar infections from 2004 to 2007.

Peritonsillar abscesses rarely occur in young children but most frequently occur in patients in their teens and early 20s. In a 5-year study of 1010 incident head and neck infections, the median (interquartile range) patient age was 13 years for peritonsillar abscesses (range, 9 to 17 years), 2 years for retropharyngeal abscesses (range, 1 to 6 years), and 6 years for parapharyngeal abscesses (range, 5 to 7 years).⁹² Retropharyngeal and parapharyngeal abscesses are more common in boys,^{34,42,53,60} whereas peritonsillar abscesses occur equally among boys and girls.⁸⁵ Retropharyngeal abscesses most commonly occur in the winter and spring,^{42,53,60,92} whereas peritonsillar abscesses have been reported to be more common in the autumn and spring⁹³ and the spring and summer.⁹²

PERITONSILLAR ABSCESS (QUINSY)

A peritonsillar abscess (quinsy) is circumscribed medially by the fibrous wall of the tonsil capsule and laterally by the superior constrictor muscle. Pus may be localized in the superior pole, midpoint, or inferior pole or rarely may be dispersed, with multiple loculations in the peritonsillar space. The superior pole is the most common location, with a frequency range of 41.2% to 70%; the remaining inferior locations account for the balance.^{10,14,66}

The etiology of peritonsillar abscesses is not constant. The abscesses may occur after any "virulent" tonsillitis, with extension through the fibrous tonsil capsule. Results of a meta-analysis of 15 previously reported

deep neck space infection,
peritonsillar abscess,
retropharyngeal abscess,
parapharyngeal abscess

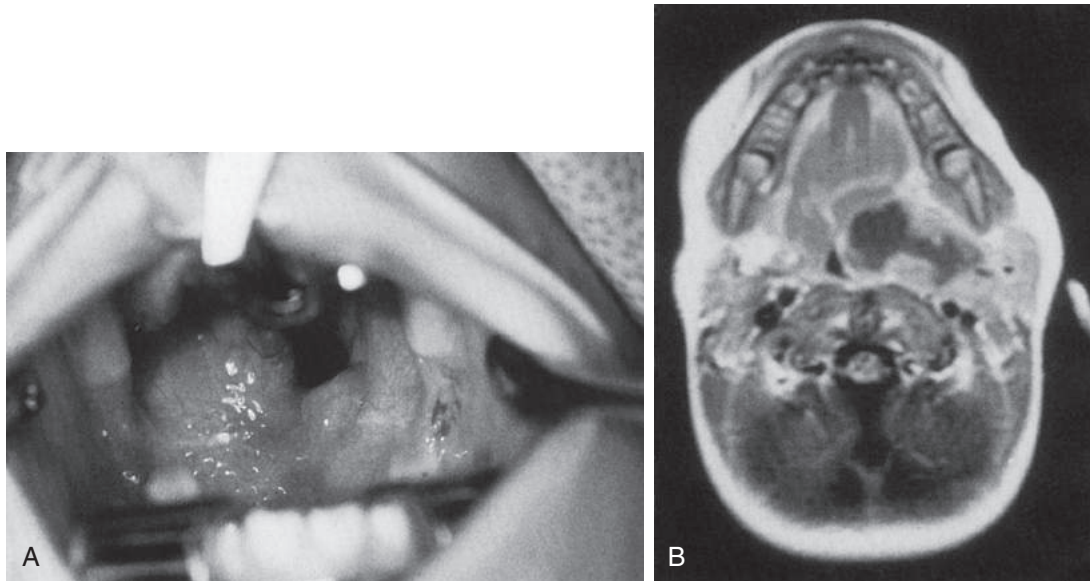

FIG. 11.1 Left peritonsillar abscess in an 18-month-old child. (From Wiatrak BJ, Woolley AL. Pharyngitis and adenotonsillar disease. In: Cummings CW, Flint PW, Harker LA, et al., editors. *Otolaryngology: head and neck surgery*. 4th ed. Philadelphia: Elsevier; 2005:4144.)

series of patients with peritonsillar abscess reported by Herzon⁴⁷ found prior tonsillar infection rates ranging from 11% to 56%, with an overall rate of 36%. Group A β -hemolytic streptococcus has a moderate role in the development of peritonsillar abscesses because throat cultures are only positive in 18% of patients,¹⁰⁰ rapid antigen tests are only positive in 20% to 30% of patients,⁸⁶ and abscess cultures demonstrate group A β -hemolytic streptococcus in 46%.³⁶

Clinical Manifestations

The patient's recent history may include a sore throat with occasional unilateral ear pain, malaise, low-grade pyrexia, chills, diaphoresis, dysphagia, reduced oral intake, trismus, and a muffled "hot potato voice." Trismus results from irritation and reflex spasm of the internal pterygoid muscle. Impaired palatal motion from edema contributes to the muffled voice.

Physical examination reveals minimal to moderate toxicity, dehydration, and drooling. Inspection of the oropharynx may be compromised by trismus. The soft palate is displaced toward the unaffected side, swollen and red, and frequently palpably fluctuant. The edematous uvula is pushed across the midline (Fig. 11.1). The displaced tonsil and its crypts rarely are coated with exudate. The breath is fetid, and ipsilateral, tender, cervical adenopathy is present. The white blood cell count is elevated, with a predominance of polymorphonuclear leukocytes.

Brodsky and associates¹⁵ attempted to identify the clinical signs that might distinguish peritonsillar abscess from peritonsillar cellulitis in a group of 21 children admitted to the Children's Hospital of Buffalo from 1985 through 1987. No significant difference in age, duration of sore throat, fever, or white blood cell count was noted, although a greater degree of pharyngotonsillar bulge and muffled voice was found in the patients with abscess. Patients with peritonsillar cellulitis improved after receiving 24 hours of intravenous antibiotics, whereas patients with peritonsillar abscess had no change or worsening of symptoms. Blotter and colleagues¹¹ confirmed these findings in 102 patients admitted to Children's Hospital of Columbus, Ohio, between 1995 and 1998.

In uncomplicated cases involving adults and older children, computed tomography (CT) has not been as useful as clinical assessment and follow-up evaluation in the management of peritonsillar abscess. CT is useful in young children with suspected peritonsillar abscess who are not cooperative with examination or children with other suspected deep neck infections.³⁹ In a retrospective study by Baker and associates,⁴ CT was ordered in 96 (64.9%) of 148 patients presenting to the emergency

department for evaluation of a potential peritonsillar abscess between 2007 and 2009. Recently ultrasonography has been investigated as a tool that avoids undue radiation exposure. Fordham and associates³⁷ found that transcervical ultrasonography had a sensitivity of 100% and specificity of 76.5% in diagnosing peritonsillar abscess in a study of 43 patients aged 2 through 20 years. While similar results for intraoral ultrasonography has been found in adults, the intraoral route may not be well tolerated in children due to their smaller mouth opening and lack of cooperation.⁷⁹

Treatment

Traditionally management of peritonsillar abscess in children involved hospital admission for intravenous hydration, antibiotic therapy, analgesia, and either intraoral incision and drainage of the abscess or "acute quinsy tonsillectomy" with removal of the medial wall of the abscess. Although older children may tolerate incision and drainage under local anesthetic, the procedure is not well tolerated in young children and carries the risk of potential injury to adjacent vascular structures. The administration of a general anesthetic is required for tonsillectomy in all age groups and often is required for incision and drainage in young children. Acute tonsillectomy often was done to prevent future recurrence of the peritonsillar abscess.

Although it is a commonly accepted clinical observation, a high recurrence rate of peritonsillar abscess has not been well documented. A meta-analysis reported by Herzon⁴⁷ of 19 studies from the United States, Europe, and Israel involving 1399 patients found recurrence rates of 10% to 15% for peritonsillar abscess. The rates of recurrence seem to be lower in the United States (0% to 17%) than in the series reported from Europe and Israel (3% to 22%). A retrospective analysis of 290 patients treated for peritonsillar abscess found that patients who had a history of recurrent tonsillitis before development of the abscess had a fourfold greater rate of recurrence than patients with no history (40% vs. 9.6%).⁵⁹ The authors recommended that patients with a history of recurrent tonsillitis before admission be treated with tonsillectomy.⁵⁹ A nationwide study in Taiwan from 2001 to 2009 involving 28,837 patients found an overall recurrence rate of 5.2%, with a rate of 6.7% in patients younger than 30 years.¹⁰⁷ The rate increased to 13.7% in patients younger than 30 years with five or more prior episodes of tonsillitis compared to 4.4% in those with less than five episodes. Evaluation of 4199 patients with peritonsillar abscess identified in a database of hospital discharge records in Veneto, Italy, found a recurrence

rate of 11.7% in patients not initially treated with tonsillectomy.¹³ This rate increased to 32% and 40% after the second or third recurrence of the peritonsillar abscess, respectively.

The risks of acute tonsillectomy are not greater than the risks associated with delayed tonsillectomy.^{65,73,111} In addition, the morbidity caused by two hospitalizations involving two procedures is reduced by acute tonsillectomy.^{7,12,14} An additional benefit of acute tonsillectomy is the ability to evacuate inferior pole abscesses that technically are difficult to drain by needle aspiration or incision and drainage.⁶⁶ Simon and associates⁹⁶ found no significant differences in total length of hospital stay, blood loss, operative time, and postoperative complications between 23 children treated by acute quinsy tonsillectomy and 11 children treated with initial antibiotics with or without incision and drainage followed by interval tonsillectomy between 2007 and 2011.

Studies have suggested that many peritonsillar abscesses can be managed by simple needle aspiration combined with antibiotic therapy on an outpatient basis.^{15,47,82,90,91,99,105,108} An extensive meta-analysis of 10 studies conducted from 1961 through 1994 involving 496 patients with peritonsillar abscesses found that needle aspiration had an overall success rate of 94% (range, 85% to 100%).⁴⁷ This success rate compares favorably with that reported for incision and drainage. Weinberg and associates¹⁰⁸ successfully performed needle aspiration in 41 of 43 children 7 to 18 years old (mean age, 13.9 years). All were admitted for intravenous antibiotic therapy, 2 (5%) required repeated aspiration for resolution, and 5 (12%) did not respond and required acute tonsillectomy. A pooled analysis of three prospective studies comparing needle aspiration versus incision and drainage showed no significant difference in resolution rates (93.7% for incision and drainage and 91.6% for needle aspiration), but the power was low because of the small sample size.⁵² Other studies, which have included adults and children with peritonsillar abscesses, have reported that 0% to 48% of patients require hospitalization.^{47,73,82,99}

Younger children often require admission to correct dehydration.³⁹ Younger children also are more likely than are older children to respond to intravenous antibiotics alone and to have negative findings at surgical drainage.¹¹ The use of conscious sedation has been reported to be a safe and effective approach for the drainage of peritonsillar abscesses in children.^{68,101}

In a 10-year retrospective review of 83 children with peritonsillar abscesses by Schraff and colleagues,⁹¹ 65% were treated by incision and drainage (51% knife vs. 14% needle aspiration), 31% had quinsy tonsillectomy, and 4% were admitted and treated with intravenous antibiotics alone. Of patients treated surgically, 51% of the procedures were done in the emergency department and 49% were done in the operating room. Forty-eight percent of the children required admission, and the average length of stay was 0.9 days (standard deviation, 1.37 days).

A suggested approach to the management of children with peritonsillar abscess is as follows.⁴⁸ Cooperative children should undergo needle aspiration of the abscess and treatment with antibiotics. Children who can tolerate liquids orally may be managed as outpatients, and the remainder should be admitted for hydration and administration of intravenous antibiotics. Approximately 4% of children require a repeated aspiration for resolution.⁴⁷ Children who remain symptomatic after undergoing needle aspiration require incision and drainage or acute quinsy tonsillectomy, depending on the prior history of recurrent tonsillitis. Children who cannot tolerate needle aspiration on initial presentation are admitted for administration of intravenous antibiotics. If no response occurs within 24 hours, incision and drainage or acute tonsillectomy is done, depending on the prior history of recurrent tonsillitis. Delayed tonsillectomy is reserved for children who recover from the peritonsillar abscess without general anesthesia but have a history of recurrent tonsillitis or prior peritonsillar abscess.

There are new data suggesting that corticosteroids may be beneficial for patients with peritonsillar abscesses. Ozbek and associates⁸³ randomized patients aged 16 to 65 years to antibiotics with a single dose of intravenous corticosteroid or antibiotics with a single dose of placebo after needle aspiration. The patients who received corticosteroids demonstrated significant improvements in throat pain, fever, trismus, and hospitalization time compared with control patients. Additional studies in children are needed to support their routine use.

Untreated peritonsillar abscess may point, with spontaneous rupture, or extend to the pterygomaxillary space, with potentially fatal complications. Upper airway obstruction, septicemia, and vascular catastrophe may occur. Necrotizing fasciitis also has been reported in adults with peritonsillar abscess.^{41,109}

RETROPHARYNGEAL ABSCESS (POSTERIOR VISCERAL SPACE, RETROVISCERAL SPACE, AND RETROESOPHAGEAL SPACE ABSCESSSES)

The anterior wall of the retropharyngeal space is the middle layer of the deep cervical fascia that abuts the posterior esophageal wall (the superior pharyngeal constrictor muscle). The deep layer of the deep cervical fascia circumscribes the posterior wall of this potential space. Inferiorly, these two fasciae fuse to limit the depth of this pocket at a level between the first and second thoracic vertebrae. A retropharyngeal abscess can erode inferiorly through the junction of these fasciae to extend posteriorly into the prevertebral space (Fig. 11.2). Subsequently, pus in the prevertebral space can descend inferiorly below the diaphragm to the psoas muscles.

The retropharyngeal space contains two paramedial chains of lymph nodes that receive drainage from the nasopharynx, adenoids, posterior paranasal sinuses, middle ear, and eustachian tube. These structures are prominent in early childhood and atrophy at puberty.⁴³ Retropharyngeal abscesses are common occurrences in young children and are thought to be secondary to suppurative adenitis of these retropharyngeal nodes.⁶ Other sources of infection are penetrating foreign bodies, endoscopy, trauma, pharyngitis, vertebral body osteomyelitis, petrositis, dental procedures,¹⁰⁵ and branchial cleft anomalies.⁵¹ In one series of 17 cases of retropharyngeal abscesses at the Children's Hospital, Denver, Colorado, seven children (41%), including two neonates (most likely associated with attempts at intubation), had perforations of the hypopharynx or esophagus.⁷⁵ In a series of 117 children with head and neck space infections treated at the Children's Hospital of Pittsburgh, 63% of the children with retropharyngeal abscesses had antecedent tonsillitis, pharyngitis, or viral upper respiratory tract infection.¹⁰⁵ Two children had previous trauma; however, no details on the type of trauma were given. In adults, tuberculosis and syphilis were common causes of retropharyngeal abscesses in the preantibiotic era.⁷⁸

Clinical Manifestations

The symptoms of retropharyngeal abscess frequently begin insidiously after mild antecedent infection. Signs and symptoms include sore throat, fever, limitation of neck motion, torticollis, neck pain, neck mass, drooling, odynophagia, poor oral intake, and lethargy. Airway stridor or respiratory distress from edema, cellulitis, or an obstructing mass occasionally occurs.^{26,27,30,106} Limited neck motion or torticollis is reported in 50% to 80% of patients.^{27,42,84} In adults, the symptoms may be milder. Complaints of chest pain may reflect mediastinal extension.

Early in the course, midline or unilateral swelling of the posterior pharynx occurs. Later, gentle palpation may show a large fluctuant mass in the posterior pharynx. Vigorous palpation should be avoided because it may cause the abscess to rupture into the upper airway. As with other abscesses, the white blood cell count is increased, with a predominance of granulocytes.

Plain films of the neck may be performed initially but must be obtained with the patient in a true lateral position, with the neck in extension and on inspiration, or the child's retropharyngeal soft tissues may appear abnormally thickened. Widening of the prevertebral soft tissues exceeding the anteroposterior diameter of the contiguous vertebral bodies or thickening of the retropharyngeal space greater than 7 mm at C2 in children and adults or 14 mm at C6 in children or 22 mm at C6 in adults suggests retropharyngeal inflammation. Rarely a prevertebral soft tissue mass, air-fluid level, or gas may be seen. The normal cervical lordosis may be lost or reversed secondary to muscle spasm or local inflammation.

CT has rendered the diagnosis and management of deep neck space infections more precise.^{16,33,57,62,103,106,110} In contrast to conventional radiologic studies, CT distinguishes cellulitis of the neck, which usually does not require surgical treatment, from a deep neck abscess, which

FIG. 11.2 (A) Oblique transverse section of the oropharynx posterosuperiorly and the hypopharynx anteroinferiorly. Depicted are a peritonsillar abscess on the right and a pterygomaxillary space abscess on the left. (B) The “cone” of the potential pterygomaxillary space with its carotid sheath. (C) The vertical dimensions of the retropharyngeal space (asterisk). The black oblique line represents the level of the drawing in (A).

FIG. 11.3 Appearance on computed tomography scan of a focal, ring-enhancing retropharyngeal abscess with a scalloped contour to the abscess wall. (From Kirse DJ, Roberson DW. Surgical management of retropharyngeal space infections in children. *Laryngoscope*. 2001;111:1416.)

generally does require surgical drainage. With its ability to define differences in tissue density, CT permits an accurate determination of the extent of the abscess and its extension and involvement of adjacent spaces to be made. An abscess is distinguished from cellulitis by a low-attenuation homogeneous area surrounded by a ring enhancement

of contrast material (Fig. 11.3). Kirse and Roberson⁵⁷ reported scalloping of the abscess wall to be a more useful predictor of the presence of pus than ring enhancement. Freling and colleagues³⁸ reported that the presence of air within or adjacent to the fluid collection indicated an abscess in all cases. When more than one space is involved, accurate assessment of these spaces may ensure sufficient surgical drainage. Vascular structures can be identified, as can potential complications such as venous thrombosis.

A 10-year retrospective study from the Massachusetts Eye and Ear Infirmary compared preoperative CT scans with intraoperative findings in 38 patients who underwent surgical exploration of the parapharyngeal or retropharyngeal space within 48 hours after the scans were performed.⁶² Overall the intraoperative findings confirmed the CT scan interpretation in 76.3% of the patients. Of the 38 patients, five (13.2%) had CT scans indicative of abscesses that were not confirmed at surgery. Exploration of the parapharyngeal or retropharyngeal space revealed cellulitis. The false-negative rate was 10.5%. The sensitivity of CT for detection of parapharyngeal or retropharyngeal space abscess was 87.9%. Additional studies have reported that the accuracy of CT in predicting surgical findings was 63%, 69%, 73%, 76%, 76%, and 92%.^{33,42,84,98,106,110}

Treatment

The treatment of choice is administration of intravenous antibiotics and incision and drainage. If the mass is small, a peroral incision with the patient in the Rose position (supine with the neck hyperextended) may provide some drainage, but a slight risk of aspiration exists. If the mass is large and extends lateral to the great vessels, or if fever persists after peroral drainage is performed, an external incision is preferred. A tracheotomy may be required if risk of compromising the airway exists. Children may need to be kept intubated postoperatively if there is significant airway obstruction. Martin and associates⁷⁰ described four patients treated successfully by CT-guided aspiration of their retropharyngeal abscesses via a percutaneous retromandibular approach in combination with intravenous antibiotics. Three aspirations were performed after failure of surgical drainage, and one was a primary aspiration.

Posterior mediastinitis can result from the spread of infection from the retropharyngeal area into the prevertebral space. The development of mediastinitis has been found to be associated with methicillin-resistant *Staphylococcus aureus* infection (MRSA), and both mediastinitis and MRSA are more common in children younger than 2 years.^{1,5,19,24,112} Other complications may be seen when the abscess extends to the parapharyngeal space and involves the great vessels and cranial nerves.

Reports have documented that patients with small retropharyngeal abscesses may respond to treatment with intravenous antibiotics alone. Johnston and associates⁵³ treated 22 of 32 children with retropharyngeal or parapharyngeal abscesses with a trial of at least 24 hours of intravenous antibiotics. Although 13 (59%) ultimately required drainage, 9 (41%) were successfully managed medically. There were no significant differences in age or white blood cell count on admission between the two groups, but children who required drainage had significantly larger abscesses (5.38 vs. 1.53 cm³). Cheng and Elden²⁴ reviewed 178 children who presented to the Children's Hospital of Philadelphia from 2007 through 2012 with retropharyngeal or parapharyngeal abscesses. Medical therapy was the initial treatment in 159 (89.3%). Of these 118 (66.3%) were treated successfully while 41 (23.0%) ultimately required surgical drainage. Risk factors for failure of medical therapy were age younger than 51 months, white blood cell count greater than 20,700/mm³, intensive care unit admission, CT suggestive of a complete abscess, and abscess size greater than 2.2 cm. A systematic review of eight articles involving 95 patients found a pooled success rate of medical therapy of 52% (95% confidence interval [CI], 53–95%), and when children taken immediately to surgery were excluded, the success rate was 95% (95% CI, 85–100%).²¹ Close clinical follow-up is mandatory for children treated with intravenous antibiotics alone. Children who do not improve within 24 to 48 hours require surgical drainage.

Similar results were found in a prospective observational study of 111 children with retropharyngeal infections managed according to a clinical practice guideline between 2001 and 2004 at the Children's Hospital of Boston.⁸⁸ Children were triaged into one of three groups at initial presentation based on clinical symptoms and CT findings: probable cellulitis, probable phlegmon, and probable abscess. Thirty-four (30.6%) children were placed in the abscess pathway and underwent prompt incision and drainage. Frank pus was found in 29 (85.3%), intensive care unit admission was required in 13 (38.2%), and 11 (32.4%) required a peripherally inserted central catheter (PICC) line due to failure to meet discharge criteria on oral antibiotics. Seventy-two (64.9%) patients were placed in the phlegmon group, and all but four required a repeat CT after 48 to 72 hours of antibiotics. Thirty-nine (54.2%) in the phlegmon group ultimately required surgical drainage, and purulence was found in 29 (74.4%). Of the 73 patients who required surgical drainage, 70 were drained transorally, two required an external approach for extension of the abscess lateral to the great vessels, and three had transcervical incisions to drain concurrent but not connected external neck abscesses. Ten patients required repeat drainage in the operating room. Presenting signs or symptoms were not significantly different between surgically and medically managed patients; however surgical patients had higher average white blood cell counts on admission and were more likely to require an intensive care unit admission, less likely to require a PICC line, and had a shorter duration of intravenous antibiotics.

PARAPHARYNGEAL ABSCESS (PTERYGOMAXILLARY, PHARYNGO-MAXILLARY, LATERAL, AND PHARYNGEAL SPACE ABSCESES)

The potential parapharyngeal or pterygomaxillary space is an inverted conical cavity (see Fig. 11.2B) lying along an oblique axis roughly parallel to the ramus of the mandible (see Fig. 11.2C). The base of the skull at the jugular foramen forms the base of the “cone,” and its apex is at the hyoid bone (see Fig. 11.2B). The buccopharyngeal fascia, lateral to the superior pharyngeal constrictor, delineates the medial boundary, and the parotid gland and its partially dehiscant deep layer of the superficial cervical fascia form the lateral wall of this cone. The internal pterygoid muscle and mandible demarcate the cone on its anterolateral aspect. The parapharyngeal space is contiguous with the peritonsillar, submandibular,

and retropharyngeal spaces, all of which are potential avenues of egress for an extending parapharyngeal space abscess (see Fig. 11.2A).

The posterior portion of the cone contains the contents of the carotid sheath (carotid artery and internal jugular vein), cranial nerves IX through XII, and the cervical sympathetic chain. The internal pterygoid muscle and fatty connective tissue are anterior.

Involvement of these structures determines the clinical manifestations and complications of the parapharyngeal space abscess. An abscess in the posterior compartment may show medial displacement of the lateral pharyngeal wall and parotid space induration and swelling, with variable overlying facial nerve weakness, carotid artery erosion and hemorrhage,⁶¹ internal jugular vein thrombosis, decreased gag reflex and dysphagia, ipsilateral vocal cord paralysis, weakness of the ipsilateral trapezius muscle, ipsilateral lingual deviation, and Horner syndrome from cervical sympathetic chain involvement.²³

Extension of the abscess into the anterior compartment causes trismus from irritation of the internal pterygoid muscle. Induration at the angle of the jaw and medial displacement of the tonsil and pharyngeal wall also occur with an anterior compartment abscess.

By the time a patient with an abscess seeks medical attention, the source of the parapharyngeal space infection may be unclear. Reports indicate variable causes, including incompletely or inadequately treated bacterial pharyngitis, tonsillitis,^{6,69,84} peritonsillar abscess, dental infections, bacterial parotitis, otitis, mastoiditis (Bezold abscess from a mastoid tip infection traveling along the digastric muscles), petrositis, cervical adenitis with suppurative, cervical vertebral tubercular adenitis,^{9,76} foreign bodies,^{23,28} trauma, intravenous drug use,⁴⁶ branchial cleft anomalies,¹⁰² and cat-scratch disease.¹¹³ Parapharyngeal abscesses seem to be less common than are peritonsillar and retropharyngeal abscesses in children.

Clinical Manifestations

In addition to the symptoms noted in the preceding description, tender cervical swelling, induration and erythema of the side of the neck, torticollis, sore throat, dysphagia, trismus, hoarseness, malaise, chills, and diaphoresis may occur. Variable low-grade pyrexia with occasional temperature spikes occurs. Examination discloses variable toxicity, respiratory tract distress, laryngeal edema, medial displacement of the lateral pharyngeal wall and inferior tonsil pole, trismus, and, infrequently, drooling. Palpation of the neck reveals a tender, high cervical mass, initially diffuse and later fluctuant. Pharyngeal blood clots may presage erosion of the carotid artery. The complications of parapharyngeal abscesses are related to the structures involved: involvement of the carotid artery can produce hemiplegia from emboli, involvement of the internal jugular vein can lead to internal jugular vein thrombosis, and cephalad extension of the thrombosis may lead to cavernous sinus thrombosis. Internal jugular vein thrombosis is characterized by spiking temperature, toxicity with intense diaphoresis, headaches, and increased intracranial pressure. Septic pulmonary emboli occasionally are present. A pseudoaneurysm of the internal carotid artery may occur as a result of arteritis from contiguous infection and vessel wall erosion.^{29,89} The patient may present with massive epistaxis days or weeks after the initial infection. Treatment involves airway protection, control of the epistaxis, resuscitation, intravenous antibiotics, and surgical ligation or endovascular occlusion.

Extension into the retropharyngeal region by a parapharyngeal abscess may lead to a posterior mediastinitis. Airway obstruction occurring secondary to laryngeal edema and aspiration pneumonia from suppurative of the abscess into the pharynx have been reported. Initially, the parapharyngeal abscess may be difficult to differentiate from a peritonsillar abscess, but the latter usually is less toxic and has a distinct, soft palatal fluctuation.

As described for the diagnosis of retropharyngeal abscess, CT is an extremely useful tool for distinguishing parapharyngeal abscess from cellulitis and for localizing the abscess for surgical planning. Chuang et al.²⁵ reported that CT had a positive predictive value of 79.6% for a drainable abscess. The CT finding most predictive was a hypodense lesion with a diameter greater than 3 cm, whereas rim enhancement alone was not a good single predictor because its presence depended on the evolution of the abscess. In a review of 47 children who presented

with deep neck infections to the Children's Hospital of Buffalo during a 5.5-year period, CT showed that 34 (77%) of 44 patients who underwent CT had involvement of the parapharyngeal and retropharyngeal spaces.⁷⁷ The involvement of both spaces had implications for the approach to surgical drainage.

Treatment

Intravenous antibiotic therapy with incision and drainage is the primary treatment. An otolaryngologic consultation should be obtained for this potentially complex surgery of the neck. The conventional method of approaching this abscess is an external incision with sufficient exposure to provide immediate access to the common carotid artery for ligation should erosion of the carotid artery be present.⁶⁷ Intraoperative ultrasonography has been described as a useful modality to assist with external drainage of difficult abscesses located medial to the great vessels and close to the skull base.³²

An intraoral drainage procedure traditionally has been condemned because rapid access to the vital structures of the neck is impossible with this approach. Nagy and associates⁷⁷ used an intraoral approach, however, to treat successfully 21 of 22 children with either parapharyngeal or combined parapharyngeal and retropharyngeal abscesses. The authors emphasized that CT with intravenous contrast enhancement showed that all of the abscesses were located medial to the great vessels and were adjacent to the pharyngeal wall. Amar and Manoukian² retrospectively compared 15 children with parapharyngeal abscesses who underwent intraoral drainage with 10 patients who underwent external neck drainage and found no complications or recurrences in either group. The children who underwent intraoral drainage had significantly reduced anesthesia time. The duration of intravenous antibiotics and duration of hospital stay also were shorter in the children who underwent intraoral drainage, but the differences between groups were not statistically significant. Cable and coworkers²⁰ described 12 children presenting to three centers with superior parapharyngeal space abscesses medial to the great vessels who were treated successfully by intraoral drainage using CT-guided systems to assist with localization of the abscess cavity. Marques and colleagues⁶⁹ successfully drained all 11 children presenting with parapharyngeal abscesses over a 5-year period via an intraoral approach with tonsillectomy. A transnasal endoscopic approach had also been used to drain an abscess located near the skull base in a 3-year-old boy.⁶⁴

The use of CT has made it possible for some patients with parapharyngeal abscesses to be managed with intravenous antibiotics. The number of reported cases is small, however, and usually analyzed with cases of retropharyngeal abscess.^{18,77} Nagy and associates⁷⁷ used intravenous antibiotics alone to treat three (13%) of 24 children with small parapharyngeal abscesses. Sichel and associates⁹⁵ used intravenous antibiotics alone to successfully treat 12 children with infection limited to the parapharyngeal space. Close clinical follow-up is necessary for children with parapharyngeal cellulitis or small parapharyngeal abscesses that are treated conservatively with intravenous antibiotics. Surgical drainage should be performed in children whose infection does not improve within 24 to 48 hours.

In another report, Sichel and colleagues⁹⁴ reviewed the CT scans of 29 patients with infections of the parapharyngeal space and divided the patients into two groups: 22 patients with posterior parapharyngeal space infections and seven patients with anterior parapharyngeal space infections. The patients with posterior infections generally were children who responded well to intravenous antibiotics and did not develop complications. The patients with anterior infections of the parapharyngeal space more commonly were adults who required external drainage in addition to intravenous antibiotics and developed complications, including septic shock, respiratory distress, mediastinitis, pericarditis, and lung empyema. The authors suggested that the location of the infection in the fat of the anterior parapharyngeal space resulted in liquefaction of the fat, with formation of pus and rapid spread of the infection to other anatomic spaces.

MICROBIOLOGY OF DEEP NECK ABSCESES

Group A streptococci (*Streptococcus pyogenes*), viridans streptococci (including *Streptococcus anginosus* [formerly *S. milleri*]), anaerobes, and

S. aureus are the organisms most frequently associated with pharyngeal space infections. These data have been consistent for more than 30 years.* Anaerobes and group A streptococci are responsible for the gas seen on lateral neck radiographs. This finding is not surprising because the main portals of entry for pharyngeal space infections are the nasopharynx, oropharynx, paranasal sinuses, mastoid, and lower molars, all areas colonized with anaerobes.

The most complete microbiologic data available are from studies of peritonsillar abscesses. Flödstrom and Hallander,³⁶ in 1976, reported the results of bacterial cultures on aspirates of pus from 37 patients with peritonsillar abscesses. The ages of the patients were not given. Group A streptococci were isolated from 17 of these patients, whereas 15 had an increase in their antistreptolysin-O or anti-DNAase titers. Anaerobes were found in 28 of the cultures, including those of 8 patients that also disclosed the presence of streptococci. The most common anaerobic species isolated were fusobacteria (13), peptostreptococci (16), and *Bacteroides* spp. (18). Among the aerobic organisms, *S. aureus* was isolated four times, and *Haemophilus influenzae* was isolated twice. No isolates of aerobic gram-negative enteric organisms were present. Jokipii and colleagues⁵⁴ performed semiquantitative cultures of aspirated pus from 42 peritonsillar abscesses and found similar results. Group A streptococci, the aerobic bacteria isolated most frequently, were isolated in pure culture four of 10 times. Anaerobes were more abundant than were aerobes; the most important species, in frequency and quantitatively, were *Bacteroides*, *Peptostreptococcus*, and *Fusobacterium*. Most of the infections were polymicrobial, with two to seven bacteria in 83% of the specimens. Subsequent studies from the United States and Finland have reported similar findings.^{17,55,90,97}

Kieff and associates⁵⁶ found that streptococci were the most frequent isolates; group A streptococci and other non-group A β -hemolytic streptococci were present in more than 30% of patients, and α -hemolytic streptococci accounted for another 27.2%. The pathogenic role of anaerobic bacteria in peritonsillar abscesses has been reinforced by reports of complications caused by fusobacterial infection in children.^{81,87} *Fusobacterium* and *Bacteroides* spp. have been associated with septic thrombophlebitis and pulmonary emboli from the jugular veins. Recent data from Aarhus, Denmark, have found *Fusobacterium necrophorum* to be the most prevalent pathogen in peritonsillar abscesses, being isolated from 41% of cultures.⁵⁸ Of the 191 *F. necrophorum* isolates detected, 81% grew as pure culture. However patients from whom *F. necrophorum* was isolated did not have a more severe presentation or outcome but tended to be younger and did have higher neutrophil counts and C-reactive protein levels than did children with other bacteria, including group A streptococci. Recent studies from other countries including Israel, Taiwan, and Japan have not found *F. necrophorum* to be an important pathogen in peritonsillar abscesses.^{22,40,49}

Data on the microbiology of retropharyngeal and parapharyngeal abscesses in children are more limited. The organisms isolated are similar to those found in peritonsillar abscesses, but with a higher number of anaerobic species. Brook¹⁶ examined aspirated pus from 14 children, 1 to 6 years old (median age, 3 years, 2 months), with retropharyngeal abscesses. Anaerobes were isolated from all patients; they were the only organisms isolated in 2 patients (14%) and were mixed with aerobes in the remainder (86%). The predominant anaerobic species were *Bacteroides*, *Peptostreptococcus*, and *Fusobacterium*. The predominant aerobic species were α -hemolytic and γ -hemolytic streptococci, *S. aureus*, *Haemophilus* spp., and group A β -hemolytic streptococci. Seventy-one percent of the isolates were β -lactamase-positive and included all isolates of the *S. aureus* group, six of 18 of the *Bacteroides melaninogenicus* group (33%), and two of three of the *Bacteroides oralis* group.

Dodds and Maniglia³¹ reported the results of cultures from nine retropharyngeal and three parapharyngeal abscesses from children and adolescents. The organisms isolated were similar to those reported by Brook,^{16,17} but the microbiology was not as complete because the study was retrospective and not all specimens may have been processed for anaerobic culture. Streptococcal species were the isolates that occurred most frequently, followed by *S. aureus* and *H. influenzae*. One isolate each of *Fusobacterium necrophorum*, *Escherichia coli*, and *Klebsiella*

*References 3, 16, 22, 36, 40, 44, 54, 55, 97, 100, 105.

pneumoniae was found. Asmar³ performed cultures on material from 17 children with retropharyngeal abscesses; viridans streptococci were isolated from 11 of the abscesses, *S. aureus* from eight, and group A streptococci from six. The most frequently identified anaerobes were *Peptostreptococcus* spp. Overall 45 aerobic and 18 anaerobic species were identified.

Rarely retropharyngeal abscess may result from anterior extension from cervical osteomyelitis. This condition has been described with tuberculosis⁷⁸ and atypical mycobacteria causing a retropharyngeal abscess in a similar clinical setting. Barratt and colleagues⁵ reported one case of retropharyngeal abscess caused by *Coccidioides immitis* in a 24-year-old woman with Hodgkin disease. The infection also was secondary to cervical vertebral osteomyelitis. Other rare and unusual causes of deep neck abscesses include cat-scratch disease (from *Bartonella*),¹¹³ *Streptococcus pneumoniae*,⁷⁴ and Kawasaki disease.⁵⁰

Because a large variety of organisms can be found in pharyngeal space infections, obtaining adequate culture specimens is crucial. The optimal material for culture is an aspirate of the pus obtained at operation. Throat swabs or swabs of the abscess obtained after drainage usually are inadequate because of contamination with normal oropharyngeal flora. The pus, when obtained, can be transported in a capped syringe if anaerobic transport media are unavailable. Most pathogenic obligate anaerobes can survive in a purulent exudate despite extended periods of exposure to air.³⁵ A Gram stain of the exudate may provide important clues to the bacterial etiology. A Gram stain showing a mixture of organisms suggests a mixed aerobic-anaerobic infection. May and associates⁷² found evidence of biofilm matrices on scanning electron microscopy in 12 of 14 abscess walls of children with deep neck abscesses treated by surgical drainage. The presence of biofilms may explain the recalcitrant nature of these deep neck space infections.

Although use of a β -lactamase-resistant antibiotic may be necessary in the treatment of deep neck abscesses because of the presence of β -lactamase-producing bacteria, including *S. aureus* and *Bacteroides* spp.,^{16,17,105} results of two studies suggest that penicillin alone was equivalent to broad-spectrum antibiotics for treatment of peritonsillar abscesses.^{56,114} Yilmaz and colleagues¹¹⁴ compared procaine penicillin with intramuscular administration of ampicillin-sulbactam in outpatient treatment of 40 patients with peritonsillar abscesses that were drained perorally. No statistical difference in duration of symptoms and clinical recovery was found between the two groups. Kieff and associates⁵⁶ retrospectively evaluated 103 patients with peritonsillar abscesses who were treated with incision and drainage. Fifty-eight patients were treated with broad-spectrum antibiotics, including ampicillin-sulbactam, clindamycin, cephalosporins, and metronidazole, alone and in combination; 45 patients were treated with penicillin alone. All patients were hospitalized after drainage, and the clinical outcomes, including duration of hospitalization and fever, did not differ significantly between the two groups. No significant difference in the organisms isolated was found, and failure and complication rates did not differ.

No comparative treatment studies for retropharyngeal or parapharyngeal abscesses have been reported. Treatment in these cases should be based on the results of cultures, as stated earlier. Drugs that may be effective include penicillin- β -lactamase inhibitor combinations such as ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam; expanded-spectrum cephalosporins such as ceftriaxone; or penicillinase-resistant penicillins, including oxacillin or nafcillin. Cephalosporins, oxacillin, or nafcillin should be used in combination with clindamycin or metronidazole for adequate anaerobic coverage. Erythromycin and other macrolides (azithromycin, clarithromycin) are less satisfactory because of increasing macrolide resistance in

group A streptococci and less activity against *Bacteroides fragilis* and *Fusobacterium*.

A study by Hanna and colleagues⁴⁵ reported macrolide resistance in 26% of group A streptococcal isolates obtained from peritonsillar abscesses seen between August 2001 and July 2002. The routine use of aminoglycoside antibiotics is not indicated because aerobic gram-negative enteric rods rarely are found in these infections. More recently, community-acquired methicillin-resistant *S. aureus* (CA-MRSA) has emerged as a pathogen in deep neck abscesses in children, especially in the United States.^{44,104} However there can be significant geographic variation in the prevalence of MRSA.⁷¹ In areas where CA-MRSA is highly prevalent, including vancomycin as initial therapy may be indicated. Clindamycin may be an alternative, but resistance of CA-MRSA to clindamycin, including inducible resistance, has been increasing in some geographic areas in the United States.⁷¹ Antibiotic therapy is effective only in conjunction with adequate surgical drainage.

Cervical lymphadenopathy is enlargement of the lymph nodes in the neck. *Cervical lymphadenitis* implies one or more nodes are inflamed. The inflammatory response by the host is triggered by some form of injury or invasion proximal to the involved lymph node or nodes. The node becomes affected secondarily by drainage through connecting afferent lymphatic channels. The injury may be acute or chronic, infectious or noninfectious. Proper anatomic definition of the inflamed node or nodes,⁹³ combined with knowledge of the structures of the head and neck drained by them, may allow identification of a portal of entry for infectious agents, the most common cause of cervical lymphadenitis in infants and children.

Fig. 12.1 illustrates the regional lymph nodes commonly affected in infants and children with cervical lymphadenitis. The superficial cervical lymph nodes lie on top of the sternocleidomastoid muscle along the course of the external jugular vein. They receive afferents from the superficial tissues of the neck, mastoid, superficial parotid (preauricular) nodes, and submaxillary glands. Their efferents terminate in the upper deep cervical lymph nodes. The mastoid lymph nodes overlie the mastoid process of the temporal bone and receive drainage from the parietal scalp and inner surface of the pinna. The occipital lymph nodes lie on the upper part of the trapezius and receive afferents from the occipital scalp and superficial portions of the upper posterior neck. Their efferents terminate in the deep cervical glands, as do the efferents from the mastoid nodes.

The deep cervical lymph nodes lie deep to the sternomastoid muscle along the whole length of the internal jugular vein and are divided into upper and lower groups. The jugulodigastric gland, a member of the upper group, lies at the angle of the jaw below the posterior belly of the digastric muscle. The lymphoid tissue of the palatine tonsil is drained into this gland; it frequently becomes enlarged in patients with “tonsillitis” or with tuberculous infection originating from the tonsils. The larynx, trachea, thyroid gland, and esophagus drain into the lower deep cervical glands. The submental lymph nodes, which lie between the digastric muscles below the myohyoid, receive superficial and deep drainage from the anterior tongue, lower lip, and chin, from both sides of the midline. They send efferents to the submandibular and upper deep cervical glands. The submandibular lymph nodes lie adjacent to the submandibular salivary gland and receive wide, superficial drainage from the lateral aspect of the lower lip, the vestibule of the nose, the cheeks, the medial parts of the eyelids, and the forehead. Deep drainage to these nodes arises from the posterior part of the mouth, gums, teeth, and tongue and from superficial and submental lymph nodes.

Because most of the lymphatic drainage of the head and neck goes to the submaxillary and deep cervical nodes, these glands are involved in more than 80% of cases of cervical adenitis in young children. Submental and superficial cervical lymphadenitis is observed less frequently.

EPIDEMIOLOGY

The epidemiology of infectious cervical adenitis is that of its infectious agents. Although cervical lymphadenitis can be a manifestation of focal viral infections of the oropharynx or respiratory tract, often it is part of a more generalized reticuloendothelial response to systemic infection. Viruses that commonly present with prominent cervical adenitis are Epstein-Barr virus and cytomegalovirus. In children infected with human immunodeficiency virus (HIV), prominent cervical adenopathy may either herald or be a part of more generalized lymphadenopathy associated with this infection. Although human herpesvirus-6 (HHV-6), the

cause of roseola in infants (exanthem subitum), is associated with the development of a mononucleosis syndrome and cervical adenopathy in adults,⁴ lymphadenitis is not a prominent feature in children with primary infection.⁶⁴ Adenoviral and enteroviral infections are causes of generalized rather than isolated cervical lymphadenopathy. The epidemiology of cervical adenitis varies by age, geographic location, and socioeconomic status. Generally, lower socioeconomic status is associated with a higher incidence of infectious etiology in younger children.

When bacterial in origin, with the exception of group A streptococci and *Mycobacterium tuberculosis*, the agents isolated from these glands are the normal inhabitants of the nose, mouth, pharynx, and skin—*Staphylococcus aureus*, anaerobes, nontuberculous mycobacteria, *Actinomyces* spp.—and person-to-person transmission does not occur. In contrast, group A streptococci and *M. tuberculosis* infection of cervical lymph nodes results from contact with human infection by way of airborne droplets. Except in neonates, for whom male dominance has been reported in cases caused by group B streptococci,¹³ infectious lymphadenitis has no gender or seasonal predilection.^{15,41}

Any age group can be affected by cervical lymphadenitis. In neonates, *S. aureus* and group B streptococci are the most common pathogens. Suppurative cervical lymphadenitis caused by *Staphylococcus epidermidis* in an otherwise healthy infant has been reported.¹⁴² Nonetheless despite the high frequency of nasal colonization by *S. epidermidis*, it remains a rare etiologic agent. There are rare reports of *Streptococcus pneumoniae* causing suppurative adenitis in older children.¹⁰⁹ Some studies indicate that *S. aureus* has the leading role in infants,¹⁸² whereas in children, either group A streptococci or *S. aureus* is equally likely to be pathogenic.^{41,161,186} Other reports have varied regarding the relationship between age and probable etiologic agent.^{15,26}

Overall, *S. aureus* and *Streptococcus pyogenes* accounted for 65% to 89% of consecutive cases in prospectively evaluated series.^{15,41} Recent reviews indicate that *S. aureus* is more common in infants with cervical lymphadenitis, especially if suppuration occurs.^{39,40,182} Methicillin-resistant *S. aureus* (MRSA) must be strongly considered as a possible etiology because of the increased incidence of health care–acquired MRSA and community-associated MRSA (CA-MRSA) infections in the United States and elsewhere.^{23,48,54,57,68,69,72,114} and recognition that the highest rates of CA-MRSA colonization and disease are found in children.^{48,115} Many studies have shown that CA-MRSA strains predominantly cause skin and soft tissue infections, but a wide spectrum of illness is reported, and invasive CA-MRSA has been associated with a variety of clinical manifestations, including severe illness and death.^{54,68,69,72,114} Retrospective and prospective case series report an increasing incidence of CA-MRSA infections manifesting as cervical adenitis and deep neck infections.^{27,44,65,72,115,182} One single-center study found that MRSA was the infectious etiology of no head and neck abscesses from July 1999 through December 2001 but accounted for 34% of cases from January 2002 through June 2004.¹²³ In other reports of 76 and 185 children with neck abscess, MRSA was the etiologic agent in 33% and 42%, respectively, and was more likely to be found in abscesses located laterally in black patients and in infants and toddlers.^{44,182}

The epidemiology of bacterial lymphadenitis varies by geographic location. Resurgence of infection with *Yersinia pestis* in the southwestern United States in 2015 means that, in areas where it is endemic, it also must be considered in the differential diagnosis.⁷⁹ Epidemic diphtheria, reported in the Russian Federation in 1990, subsequently spread to several newly independent states in the European region, with the number of reported cases (50,425) peaking in 1995. After the implementation

TABLE 12.1 Differentiation of *Mycobacterium tuberculosis* and Nontuberculous Mycobacterial Cervical Adenitis (NTM CA)

	NTM CA	<i>M. tuberculosis</i>
Age	1–6 y	All ages
Ethnicity	White	Black, Asian, Hispanic
Exposure to tuberculosis	Absent	Present
Abnormal chest radiographs	Rare	Often
Residence	Suburban	Urban
TST >15 mm	Uncommon	Often
Positive IGRA	Unlikely ^a	Yes
Bilateral involvement	Rare	Not uncommon

IGRA, interferon-γ release assay; TST, tuberculin skin test.

^aExcept for infection with *M. kansasii*, *M. szulgai*, *M. marinum*, *M. flavescentis*.

of diphtheria control measures, the number of cases declined by more than 95% from 2000 through 2009.¹⁷⁵ However, because circulation continues in some countries in Eastern Europe and with increasing migration between countries, sporadic cases may occur even in countries with high vaccination rates.¹⁸⁰ Diphtheria also must be included as a possible cause of cervical lymphadenitis in those regions of the world.

The distinctive epidemiologic features of mycobacterial infection are summarized in Table 12.1. Scrofula caused by *M. tuberculosis* is a rare disease. When it does occur, it usually affects adults and older children. In contrast, children with nontuberculous mycobacterial infection almost always are 1 to 6 years of age, live in suburban or rural communities, and have no history of contact with *M. tuberculosis*.¹⁵⁶ Although *M. tuberculosis* is an infection acquired primarily by inhalation, the gastrointestinal tract or respiratory tract may be the primary portal of entry for nontuberculous mycobacteria.^{55,119,129,134} There seems to be an ethnic predilection for nontuberculous mycobacterial infection to occur in whites and for tuberculous infections to occur in blacks, Hispanics, Asians, and the Australian Aboriginal population.^{118,159} A recent

study of 139 children with confirmed *M. tuberculosis* cervical lymphadenitis in Taiwan demonstrated an association of a polymorphism in the mannose-binding lectin gene with this etiology, suggesting the potential role for innate immunity in the pathogenesis.¹⁸⁸

The advent of the HIV pandemic had a major impact on the nature and frequency of mycobacterial infections. The availability of highly active antiretroviral therapy (HAART) resulted in significant decreases in the incidence of opportunistic infections, including tuberculous and nontuberculous mycobacterial infections, in HIV-infected children.⁵⁶ However, cases of tuberculous and nontuberculous infection as part of an immune reconstitution syndrome in individuals started on HAART have been reported.¹

The presence of tuberculosis infection in the community means that all children are at risk for exposure to an infectious adult.²² The annual tuberculosis rate in the United States decreased steadily during the years 1993 through 2014, but the annual decline has decelerated.^{33,147} Drug-resistant tuberculosis also is increasingly detected in industrialized and developing countries, both multidrug-resistant (e.g., resistant to isoniazid and rifampin, first-line drugs in the treatment of tuberculosis) and extensively drug-resistant (resistant to isoniazid, rifampin, and three of the six classes of second-line antituberculosis drugs).^{32,181}

The incidence of nontuberculous mycobacterial infections has increased since the 1980s, although some of this apparent increase most likely has resulted from improvements in diagnostic methods. Nontuberculous mycobacteria are ubiquitous and are found in food, water, animals, and soil. An association between nontuberculous cervical adenitis and cold weather is prompted by observations that 68% of cases occur in the winter and spring months.^{55,98,127,178} A 10-year Canadian retrospective study reported that 70% of cases occurred in girls; however, most reports suggest no gender difference.¹²⁷

Until the 1970s, *Mycobacterium scrofulaceum* was the usual etiologic agent in children with nontuberculous adenitis, followed by *Mycobacterium avium-intracellulare*.¹⁷⁸ This trend has reversed, with *M. avium-intracellulare* now accounting for 50% to 98% of culture-proven cases.^{47,49,67,94,98,117,118,162,178} Previously uncommon species, such as *Mycobacterium kansasii*, *Mycobacterium mageritense* (found primarily in Europe), *Mycobacterium fortuitum*, *Mycobacterium haemophilum*, and *Mycobacterium bohemium*, also are being detected more frequently.^{8,12,126,171} Some of these uncommon species probably are responsible for many cases of culture-negative lymphadenitis because of their fastidious growth requirements. New diagnostic methods have led to increasing reports of cervical adenitis secondary to slow-growing species, such as *Mycobacterium lentiflavum* and *Mycobacterium interjectum*.^{43,62,66,71,131,154} Cervical lymphadenitis caused by *Mycobacterium chelonae* is rare, usually involves the submandibular glands, and typically occurs in patients with an antecedent history of dental pathology.⁶

Cervical lymphadenopathy may be the direct result of infection with HIV per se. However, the development of acute, tender adenitis in an HIV-infected child should provoke a search for another etiology. Although the typical childhood pathogens remain the most common pathogens in this setting, as in other immunocompromised children, opportunists also should be sought.⁶⁰ Patients with HIV infection beginning therapy with potent antiretroviral agents can develop new-onset mycobacterial lymphadenitis (tuberculous and nontuberculous mycobacteria). When this lymphadenitis occurs, it is more localized, is associated with more sinus formation, and is more often caused by nontuberculous mycobacteria (*M. avium-intracellulare*) than by *M. tuberculosis*.¹³⁰

Cat-scratch disease is a common cause of lymphadenitis in children and young adults.^{7,25} In 1988, English and associates⁴⁶ first isolated a pleomorphic gram-negative bacillus, later identified as *Afpia felis*, from lymph nodes of patients with cat-scratch disease. *Bartonella henselae*, a morphologically similar but genetically distinct pleomorphic gram-negative bacillus, now is recognized as the cause of cat-scratch disease.²⁷

The cervical nodes are the second most common site of cat-scratch disease involvement. Although unusual and severe manifestations of this infection have been described, it remains mostly a mild, self-limited infection in children and adolescents, with no ethnic predilection. Seasonal variation with an increased incidence in fall, winter, and early spring does occur in temperate zones. A history of animal contact with cats usually can be elicited.³¹ The importance of bites and scratches by

kittens in transmitting this disease has been well defined.^{7,106,189} However, the absence of a history of traumatic contact with cats in a substantial number of cases supports the hypothesis of an alternative mode of transmission. The detection of *Bartonella* DNA by polymerase chain reaction (PCR) assay in collections of fleas from cats owned by two infected patients suggests that fleas or other arthropods may serve as vectors, but their role in human transmission is not well established.^{7,187}

PATHOPHYSIOLOGY

Although cervical lymphadenitis is a common entity in pediatric clinical practice, little information exists regarding its pathogenesis. Viral cervical adenitis may be part of either a local response to viruses invading the oropharynx or respiratory tract (e.g., adenoviruses or coxsackieviruses) or a more generalized reticuloendothelial response to systemic viral infection (e.g., Epstein-Barr virus, cytomegalovirus, HHV-6, or HIV). Infection attributed to group A streptococci and *S. aureus* is presumed to enter the cervical lymphatics from the oropharynx (group A streptococci) or anterior nares (*S. aureus*). In a patient with group A streptococcal pharyngitis or tonsillitis, whether infection remains localized at the pharyngotonsillar tissues or spreads to cervical lymph nodes and results in suppuration primarily is a function of host response and probably strain virulence. Although peak attack rates for group A streptococcal pharyngitis are observed among school-age children, suppurative cervical adenitis is an uncommon occurrence. In contrast, infants and children younger than 3 years of age rarely have group A streptococci isolated from throat cultures, but this age group is more likely to develop suppurative cervical lymphadenitis.¹³³

In infections attributed to *S. aureus*, colonization of the anterior nares is thought to be a prerequisite for cervical lymphadenitis. Brook and Winter^{24,25} arrived at this conclusion because organisms of identical phage types were isolated from the anterior nares and the cervical abscesses of their patients. An investigation of children in St. Louis found no such correlation between isolates from nasal and cervical node cultures.¹⁵ The role of *S. aureus* as a primary pathogen has been the subject of some debate. In most series, 30% of aspirates yield mixed cultures of *S. aureus* and group A streptococci, and frequently significant elevations of antistreptolysin O titer are found in the sera of patients whose lymph nodes yielded a pure culture of *S. aureus*.

In a California study, 65% of patients had lymph node aspirates yielding a pure culture of *S. aureus*, and 41% exhibited an immune response to one or more of the extracellular antigens of group A streptococci.¹⁸⁶ Similarly, the finding that many children improve with penicillin or ampicillin treatment, despite the high prevalence of penicillin resistance among *S. aureus*, suggests that, although streptococci and staphylococci may coexist in these nodes, staphylococci may sometimes play a subsidiary role as secondary invaders. However, most children with isolates of *S. aureus* from suppurative lymph nodes show no evidence of coexistent streptococcal infection or viral upper respiratory tract infection. In addition, the resurgence of *S. aureus* (often MRSA) as a single pathogen in more recent case series argues that this organism has a strong capacity to be the primary invader.^{39,40,44,182}

Recovery of anaerobic bacteria from cervical nodes suggests invasion of the lymphatics by mouth flora, often as a result of local tissue destruction by periodontal disease.²⁶ The delineation of the pathophysiology of cervical lymphadenitis of diverse bacterial etiology requires an understanding of the interaction between a given microorganism (e.g., inoculum size, elaboration of extracellular enzymes, and ability to adhere to epithelium) and the host (e.g., humoral and surface immune capacity and degree of trauma).

Tuberculous cervical lymphadenopathy occurs within months of the initial exposure, through pulmonary infection and involvement of the regional and then more distant lymph nodes. It is a rapid process; chest radiographic evidence of active pulmonary disease often is seen.¹⁰ Nontuberculous mycobacteria are ubiquitous in the environment, and oropharyngeal acquisition with local infection leads to lymph node involvement. Most children with nontuberculous mycobacterial cervical lymphadenitis are immunocompetent. However, some studies suggest that children who develop necrotic nodes may have deficient production

of interferon (IFN)- γ .¹¹⁷ and disseminated infections are almost always associated with impaired T-cell function.⁸ Despite *M. avium* skin test positivity being linked with pet birds, no clear relationship with lymphadenitis has been shown.⁸⁶ Discontinuation of childhood bacille Calmette-Guérin vaccination has been associated with an increase in atypical mycobacterial infection in many countries, suggesting that this vaccine may have a protective effect.¹⁷² Progressive cervical adenitis developing after bacille Calmette-Guérin vaccination also has been reported.¹²⁰

CLINICAL PRESENTATION

The clinical manifestations of cervical lymphadenitis vary considerably but are consistent with the diverse etiologies associated with cervical node enlargement in infants and children. Categorizing the mode of presentation as acute, subacute, or chronic is useful because, although the boundaries are ill defined and much overlap exists, common etiologies tend to fall consistently within one of the categories. Cervical lymphadenitis of acute onset may be categorized further as bilateral or unilateral. In most situations, acute, bilateral cervical adenitis is either part of a generalized reticuloendothelial response to a systemic infection or a localized reaction to acute pharyngitis. The presence or absence of associated features (e.g., pharyngitis, enanthems or exanthems, generalized adenopathy, and hepatosplenomegaly) aids in making the differentiation.

Acute unilateral cervical lymphadenitis is caused by streptococcal or staphylococcal infection in 53% to 89% of cases.^{15,41,44,70,170,186,182} In newborns, *S. aureus* is the most common cause, and clinical features are similar to those seen in older children. Group B streptococci have been described as causative in a "cellulitis-adenitis" syndrome in infancy.¹³ These infants differ from infants with staphylococcal adenitis in that they are younger, are more often male, and have a greater incidence of systemic symptoms, irritability, and anorexia; 94% have associated bacteremia. The typical patient has fever, facial or submandibular cellulitis, and ipsilateral otitis media.¹³ Isolated cervical adenitis caused by group B streptococci also has been described.⁵⁰

Patients with disease attributed to *S. aureus* or group A streptococci can become ill at any age but typically are 1 to 4 years old (70–80% of cases), and the male-to-female ratio is equal. Clinically, little differentiates streptococcal from staphylococcal infections. Cervical adenitis can occur as part of the "streptococcosis" syndrome of infancy, with an onset heralded by coryza, an irregular low-grade fever, nasal discharge with excoriation and crusting around the nares, vomiting, and loss of appetite. Lymph node enlargement occurs within a few days of onset and resolves, as do other symptoms, without treatment within 6 to 8 weeks.¹³³ Suppuration of cervical glands can occur at any time during this interval but seldom does so if effective antimicrobial therapy is given early in the illness. Group A streptococci also should be suspected as a cause of cervical adenitis in a patient with typical vesiculopustular or crusted lesions of impetigo involving the face or scalp.

Systemic symptoms in children with staphylococcal or streptococcal cervical adenitis usually are minimal or absent unless associated with cellulitis, metastatic foci of infection, or bacteremia. The primary site of lymph node involvement by frequency is submandibular (50–60%), upper cervical (25–30%), submental (5–8%), occipital (3–5%), and lower cervical (2–5%).^{15,41,179} Involved nodes generally vary in size from 2 to 6 cm in diameter, and one-fourth to one-third suppurate. Patients with lymphadenitis caused by *S. aureus* are more likely to develop suppuration and a longer duration of symptoms and signs before diagnosis than are patients with disease caused by other bacterial agents (Fig. 12.2).^{15,137,141,161} Among patients who develop suppurative adenitis, the majority do so within 2 weeks of onset.

Approximately one-third of patients in one study had concomitant lymphadenopathy at other anatomic sites.¹⁵ A history of recent upper respiratory tract symptoms, including sore throat (40%), earache or coryza (16%), and impetigo (32%), is a frequent finding, as are signs of pharyngitis, tonsillitis, or otitis media.^{15,41} These factors do not help delineate the etiology, however. Hepatomegaly or splenomegaly is a rare occurrence and, if present, should suggest bacteremia or generalized disease processes (e.g., Epstein-Barr infection, reticuloendotheliosis, tuberculosis, or HIV infection).

FIG. 12.2 A 2-year-old boy with fever and unilateral inflammation of the cervical lymph nodes of 2 days' duration. Needle aspirate culture of this nonfluctuant node grew *Staphylococcus aureus*. Antistaphylococcal therapy resulted in complete resolution of adenitis without surgical drainage.

Kawasaki disease may manifest as a febrile illness associated with bilateral or unilateral cervical lymphadenopathy and may be confused with more common acute pyogenic infections.¹⁷⁴ Other features (e.g., conjunctivitis, oral manifestations, changes in the peripheral extremities, and polymorphic erythematous rash) are required criteria for the diagnosis.^{9,110} Although originally termed *mucocutaneous lymph node syndrome*, unilateral lymph node enlargement of at least 1.5 cm is the most inconsistent feature.^{9,17,110} Lymphadenopathy usually subsides when the fever subsides, although in some cases it may follow a more chronic course.

The rapid development of painful lymphadenitis, quickly succeeding the sudden onset of fever, chills, weakness, and headache, is a classic presentation of infection caused by *Y. pestis* (bubonic plague). The groin is the site most often involved. Other locations, including the cervical area, may be affected, however. Establishing the diagnosis and providing treatment quickly are crucial because infection can be fulminant.

In cases of diphtheria, cervical adenopathy develops secondary to infection of the posterior structures of the mouth and proximal pharynx. A whitish gray membrane covers the mucosal surfaces. In severe cases, the cervical adenopathy, which typically is bilateral, can result in a "bull neck" appearance.

Careful physical examination of the head and neck, particularly areas drained by affected lymph nodes, may yield important clues about etiology. The presence of periodontal disease is associated with a higher incidence of anaerobic organisms causing adenitis,²⁶ the history or presence of tick bites suggests the possibility of tularemia,¹⁵³ and the presence of papular or pustular lesions suggesting an inoculation site raises the possibility of other causes of infection, including *Nocardia* and *Bartonella* spp., actinomycosis, sporotrichosis, plague, and cutaneous diphtheria.

Mycobacterial and *Bartonella* spp. infections and toxoplasmosis are more common entities presenting as subacute or chronic lymphadenitis. The epidemiologic and clinical features that aid in the differentiation of tuberculous and nontuberculous mycobacterial infections are summarized in Table 12.1. The clinical manifestations virtually are identical (Fig. 12.3).^{8,10,21,33,112} Typically a child presents with a history of painless (so-called cold) cervical node swelling. The submandibular cervical nodes usually are involved in nontuberculous mycobacterial infection, whereas other cervical nodes are involved more frequently with *M. tuberculosis*.^{5,21,74,105,144} As the infection progresses, the skin overlying the node may develop a pinkish or violaceous discoloration caused by increased vascularity, although the skin temperature usually is not increased. This finding may be followed by adherence of the skin to

FIG. 12.3 A 4-year-old boy who had bilateral nontender enlargement of lymph nodes of 6 weeks' duration, without other symptoms. Placement of a tuberculin skin test resulted in 18-mm induration, excisional biopsy acid-fast stain was positive, and cultures grew *Mycobacterium tuberculosis*.

the underlying mass. If left untreated, fluctuance and spontaneously draining sinus tracts may develop.

A patient with *M. tuberculosis* is more likely than one with atypical mycobacterial disease to be older than 4 years of age and to have generalized lymphadenopathy (10–20% of cases), bilateral node enlargement (10% of cases), a history of exposure to tuberculosis (93% of cases), and an urban residence.^{21,80,105,122} No differences have been noted, however, with regard to duration of adenopathy, fever, and presence or absence of constitutional symptoms. An abnormal chest radiograph has been noted in 28% to 71% of cases caused by *M. tuberculosis*,^{144,145,158,170} contrasting with the 98% to 100% of normal chest radiographs found in patients with nontuberculous mycobacterial adenitis.^{55,143,144,162,169}

In a summary of 447 reported childhood cases of nontuberculous mycobacterial infections from 15 countries, Lincoln and Gilbert⁸⁵ detected only six cases of bilateral cervical node involvement, four with abnormal chest radiographs, and none with nodal enlargement other than cervical. Similar findings have been reported by other investigators.^{143,169} Intradermal tuberculin skin testing with purified protein derivative uncommonly produces more than 15 mm of induration at 48 hours in a child with nontuberculous mycobacterial infection, but reactions between 5 and 15 mm are common.^{90,101} Reactions of 10 to 20 mm can occur with *Mycobacterium marinum* and *M. fortuitum* infection.¹²⁹ Tuberculin skin test positivity may persist, even when children are retested many years after infection.¹⁷⁸ Unlike the findings with tuberculosis, IFN- γ release assays generally are negative with nontuberculous mycobacterial infections unless the infecting organism is *M. kansasii*, *Mycobacterium szulgai*, *M. marinum*, or *Mycobacterium flavescens*, which share some antigens that react in the assay and may cross react.^{10,157}

Bartonella infection may manifest days to weeks after the initial inoculation. Characteristically a history of contact with a cat or kitten or a scratch is present.^{7,189} Later, when the primary small papular lesion may have healed, tender regional adenopathy appears. Although axillary nodes most frequently are affected, 25% of children have isolated cervical node involvement. Middle cervical and parotid nodes are involved more often than submandibular nodes.¹³⁸ Constitutional symptoms, present early in the course of the illness, usually are mild and may have resolved by the time the adenitis appears. Fever is observed in one-fourth of patients and, if present, has a mean duration of 5 to 7 days.¹⁰⁰ Fever prolonged beyond this time should prompt evaluation for characteristic hepatosplenic granulomatous lesions defined by

high-resolution ultrasonography with disseminated cat-scratch disease. Nodes suppurate in one-tenth to one-third of patients.^{31,32} Rare manifestations include Parinaud oculoglandular syndrome,²⁹ encephalopathy,⁹⁷ exanthems³¹ (usually of the erythema nodosum type), and osteolytic lesions.³⁰

Acquired toxoplasmosis may manifest as regional lymphadenopathy, frequently with posterior cervical node involvement.^{108,136,167} Most children exhibit few, if any, constitutional symptoms. If present, fatigue and generalized myalgia are prominent. The characteristic location combined with a history of exposure to cats or of eating undercooked meats should raise this diagnostic possibility, and the diagnosis can be confirmed by serologic testing. It is an uncommon etiology for cervical adenopathy in children living in the United States.

Chronic, recurrent cervical adenitis forms part of the periodic fever, aphthous ulcers, pharyngitis, cervical adenitis (PFAPA) syndrome, a chronic syndrome first described in 1987.¹⁰⁷ It is characterized by periodic episodes of high fever, greater than 39°C (102.2°F), lasting 3 to 6 days and recurring every 3 to 8 weeks in association with aphthous ulcers, pharyngitis, and cervical adenitis. Symptoms such as abdominal pain, nausea, diarrhea, and headache also are described in 20% to 73% of children,¹⁶⁸ but if any of these are the dominant features, other hereditary fever syndromes should be excluded.⁵³ In most children with PFAPA, the onset of disease occurs before they reach 5 years of age, the syndrome is self-limited, and recovery without long-term sequelae is the rule.¹⁸⁵ Although there appears to be a familial predisposition for PFAPA, to date no single gene trait has been found, suggesting that this condition may have a heterogeneous, polygenic, or complex inheritance.⁷⁷ Oral corticosteroids are effective in aborting an attack.^{83,124,168}

Kikuchi-Fujimoto disease, also called *subacute necrotizing lymphadenitis*, is an uncommon disorder of uncertain etiology that also may manifest as cervical adenopathy, with or without fever. This disorder was described first in 1972 and seems to have a predilection for Asian women 25 to 30 years of age, who generally have a benign course with spontaneous resolution over 3 to 4 months.^{52,173} Kikuchi-Fujimoto disease also has been reported in children, typically adolescents, although cases in children as young as 2 years old are documented.^{38,82,84,176}

In contrast to the 4:1 female predominance documented in adult series, pediatric Kikuchi-Fujimoto disease occurs more commonly in boys (male-to-female ratio ranges from 1.2:1 to 1.9:1). The most common presentation is unilateral or bilateral lymphadenopathy of multiple nodes. In most cases, posterior cervical chain nodes are involved, and affected nodes can be painful and tender. Fever is an inconsistent symptom. Extranodal manifestations include malaise, night sweats, weight loss, maculopapular skin rashes, gastrointestinal symptoms, hepatosplenomegaly, arthritis, and aseptic meningitis. Associated laboratory findings include leukopenia (33% to 100% of cases with prolonged fever), elevated erythrocyte sedimentation rate, mild anemia, elevated C-reactive protein, and elevated liver enzymes.

Diagnosis is established by biopsy of the lymph nodes (not by fine-needle aspiration cytology) which shows lymphadenitis with focal proliferation of reticular cells accompanied by histiocytes and extensive nuclear debris. Lymph node biopsy also has been associated with prompt resolution of fever.³⁸ Treatment generally is supportive, although steroids are reported to provide more rapid resolution of symptoms. The prognosis is favorable; most cases of Kikuchi-Fujimoto disease resolve within 6 months, although a recurrence rate of 3% to 4% is recorded. Some children subsequently develop autoimmune disorders, most commonly systemic lupus erythematosus; thus clinical follow-up looking for signs of evolving autoimmune disorder is recommended.^{37,116,150,176} Whether Kikuchi-Fujimoto disease is infectious or genetic, perhaps the result of infection with a single novel agent or a nonspecific host response to any of a variety of agents, remains to be determined.

Another rare but important cause of cervical lymphadenitis in association with generalized lymphadenopathy or hepatosplenomegaly is hemophagocytic lymphohistiocytosis, also known as hemophagocytic syndrome. This diagnosis should be considered if the aforementioned features occur with prolonged fever, cytopenia in at least two cell lines, low fibrinogen, and high ferritin and triglyceride serum levels.¹²⁵ Other features include rash, respiratory distress, hypotension, and coagulopathy. The diagnosis is confirmed by the presence of hemophagocytosis in

bone marrow or lymph node biopsy specimens. Finally, when presented with a history of subacute or chronic lymphadenitis, careful physical examination should be undertaken to exclude obvious local causes (e.g., seborrhea, head lice, tinea capitis, and chronic otitis media) before an extensive diagnostic evaluation is initiated.

DIFFERENTIAL DIAGNOSIS

Cervical swellings are encountered frequently in pediatric practice, and most of them represent lymph nodes. When considering the diagnostic possibilities in patients with cervical lymphadenitis, whether the pathologic process involves a lymph node first must be ascertained, then whether its cause is infectious, and, if infectious, the likely etiologic agent. The duration of the cervical swelling aids in the differential diagnosis because most tumors or developmental anomalies have been noted for weeks. Rapid enlargement may occur in the latter entities but usually as a result of secondary infection. Location is a helpful clue because midline masses rarely represent lymph nodes, and the most common neck masses of congenital origin (thyroglossal duct cyst, branchial cleft cyst, and cystic hygromas) have characteristic anatomic locations.

Of the midline masses, thyroglossal duct cysts are the most common.^{75,132} These cysts occur from the foramen cecum to the thyroid, are midline, and move on protrusion of the tongue. They may have an associated sinus tract, midline or just lateral to it, from which cloudy mucus sometimes can be expressed. They can become infected secondarily, but in the noninfected state these cysts are nontender, smooth, and round, with well-defined margins. Thyroglossal duct cysts must be differentiated from other midline masses, including epidermoid cysts, lipomas, thyroid tumors, and the rare midline lymph node.

The second most common benign congenital neck mass is the branchial cleft cyst. It usually arises from the second branchial cleft and lies at the anterior border of the sternocleidomastoid muscle. Although such cysts usually manifest as skin dimples, they may become infected secondarily and manifest as inflammatory swellings or draining sinus tracts. A careful examination should detect a sinus tract. Branchial cleft cysts can manifest in individuals of any age but usually occur in school-aged children.

Cystic hygromas, considerably less common than thyroglossal duct or branchial cleft cysts, are the third most frequent cause of congenital neck masses. These arise from lymphatics derived from the jugular vein or the mesenchymal tissue. They can occur elsewhere but usually are found posterior to the sternocleidomastoid muscle in the supraclavicular fossa. Most cystic hygromas appear in the first 2 years of life, many being noted at birth or soon thereafter. They are soft, compressible tumors that transilluminate well, and, although benign in themselves, they may cause symptoms through pressure exerted on surrounding structures. Confusion may arise when cystic hygromas increase in size in association with an upper respiratory tract infection. The latter process causes increased lymph flow so that the hygroma persists while other lymph nodes decrease in size after resolution of the infection. In most circumstances, palpation and transillumination readily distinguish these congenital malformations.

These four cervical masses—thyroglossal duct cysts, thyroid tumors, branchial cleft cysts, and cystic hygromas—accounted for 63.7% of lesions in children with persistent cervical masses reported by Moussatos and Baffes.¹¹² Other lesions included neurogenic tumors, parotid tumors, and miscellaneous benign tumors (12.3%). The remainder of masses represented lymph nodes. As a rule, masses located completely anterior to the sternocleidomastoid muscle are benign. The exception is the thyroid tumor.¹¹² Malignancies that mimic cervical lymph nodes usually are located in the posterior triangle or are multiple masses extending across the anterior and the posterior triangles. In contrast, approximately 50% of masses in the posterior triangle represent malignancies, most of which are of lymphoid origin. Although most cysts and tumors manifest as solitary, unilateral, nontender masses, lymph nodes of noninfectious etiology frequently are multiple and bilateral and may be mildly tender.

Noninfectious chronic inflammatory involvement of cervical lymph nodes may represent a variety of uncommon, usually benign, but sometimes malignant entities (Table 12.2). Fifty percent of malignant

neck masses in children are caused by Hodgkin and non-Hodgkin lymphomas. Neuroblastoma is the second most common malignancy, accounting for 15%. The likelihood of a given diagnosis is age dependent, with neuroblastoma being more common than Hodgkin disease in younger age groups.⁷⁰ Thyroid tumors are the third most frequent neck malignancies. Other entities to be included in the differential diagnosis include leukemia,²⁸ metastatic carcinoma,¹¹² phenytoin-induced pseudolymphoma,²⁸ serum sickness,²⁸ storage disorders (Gaucher disease and Niemann-Pick disease), collagen vascular disease,²⁸ sarcoidosis,⁷³ sinus histiocytosis with massive lymphadenopathy,^{14,140} and reticuloendotheliosis or histiocytosis X. Except for malignancies, these disease entities almost always are associated with lymphadenopathy that is not limited to the cervical region and have a variety of clinical and laboratory findings that allow the correct diagnosis to be made.

Numerous infectious agents have been reported in association with cervical adenitis in infants and children (Table 12.3). Among patients evaluated prospectively with needle aspirate cultures or cultures from incision and drainage specimens of affected lymph nodes, *S. aureus* or group A streptococci are the organisms most frequently isolated.^{15,26,41,44,161,186} No significant difference has been reported that distinguishes between patients with adenitis caused by streptococci or staphylococci with respect to sex, dental problems, symptoms, presence of fever, or site or size of lymph nodes. In patients from whom *S. aureus* is isolated, a longer

duration of disease before diagnosis is established, and a larger percentage of fluctuant lymph nodes^{15,161} and tendency toward slower resolution often are found. Two recent studies reported that *S. aureus* was more common in infants younger than 12 and younger than 16 months of age, respectively, than in older children with neck abscesses and also noted a predominance of CA-MRSA among black children.^{44,182} Most patients with bacterial cervical lymphadenitis, including patients with mycobacterial infection, are 1 to 6 years of age. Older children are more likely to have negative lymph node aspirate cultures.^{15,152,161}

In early studies, anaerobes rarely were associated with cervical adenitis.^{15,41,183} Proper bacteriologic techniques for the isolation of these fastidious organisms allowed Brook²⁶ to report anaerobes alone in 18% and mixed anaerobic and aerobic bacteria in 20% of patients, suggesting that anaerobic organisms play a more significant role in the etiology of cervical lymphadenitis than recognized previously. An older child with “negative” cultures, especially a child with poor dental hygiene or periodontal disease, may have anaerobic infection, as did the 9-year-old boy in Fig. 12.4. Needle aspiration of this cervical mass yielded *Peptococcus* and *Peptostreptococcus* spp., *Bacteroides fragilis*, and viridans streptococci. Resolution of the lymphadenitis occurred promptly after incision and drainage and penicillin therapy.

Dental disease or manipulation, or oral trauma, also should suggest the possibility of cervicofacial actinomycosis (lumpy jaw), an uncommon

FIG. 12.4 A 9-year-old boy who developed high fever and markedly tender submental lymph node inflammation after a tooth extraction. Cultures from this fluctuant mass grew three anaerobes and viridans streptococci.

entity in children.¹⁶⁶ These patients may be older and have an indolent presentation, chronic submandibular mass, and frequently a fistula from the skin to the oral cavity.¹⁸ Less frequently occurring bacteria,⁸¹ viruses, fungi, and parasites can cause cervical lymphadenitis in children, but these patients usually have less evidence of acute inflammation, with or without adenopathy at additional sites, and historical and physical findings that suggest unusual causes of cervical lymph gland enlargement.

SPECIFIC DIAGNOSIS

A detailed history to ascertain preceding dental problems, presence of skin lesions, animal exposure (including exposure to fleas and ticks), duration of illness, presence of associated symptoms, contact with tuberculosis, presence of risk factors for HIV infection, drug usage (especially phenytoin), unusual ingestions (e.g., undercooked meat or unpasteurized dairy products), recent travel outside the geographic region of residence, and sites of occult infection drained by the affected node may yield important diagnostic clues in a patient with cervical lymphadenitis. Physical examination should include careful inspection for the presence of dental disease, noncervical lymphadenopathy, hepatosplenomegaly, and oropharyngeal or skin lesions.

Radiologic evaluation of adenitis is unnecessary in most mild to moderate cases. Ultrasonography often is performed when the presenting neck mass is very large, is increasing in size, or has not responded to initial antibiotic therapy. It is useful in diagnosing suppuration and expediting incision and drainage. High-resolution and color Doppler ultrasonography (with or without contrast enhancement) defining longitudinal to transverse nodal ratio and vascularity patterns has had some success in differentiating benign and malignant lymph nodes in adults.^{3,111,113,184,187}

In children in whom most adenopathy is infectious or reactive in etiology, ultrasonography is less discriminating. In one study of 35 children, ultrasonography showed significant differences in lymph nodes in 22 children with a diagnosis of Kawasaki disease in contrast to 8 children with bacterial lymphadenitis, but findings were similar to those in children with lymphadenitis caused by Epstein-Barr virus infection.¹⁶⁴

In another study of 146 children, unilateral lymph nodes and cystic necrosis were found only in lymphadenitis caused by cat-scratch disease or bacterial or tuberculous infection.¹²⁸ Individual sonographic findings were nonspecific for diagnosis, although these findings combined with clinical signs were helpful. No patients with nontuberculous mycobacterial adenitis were evaluated in this study. Nodal calcifications and spread of nodal masses into the subcutaneous tissues by ultrasonography and

characteristic low-density, ring-enhancing lesions with minimal or absent inflammatory stranding of subcutaneous fat seen on computed tomography and magnetic resonance imaging have been reported with nontuberculous mycobacterial adenitis in children.^{63,67,92,139} These findings may be helpful in differentiating this etiology from other bacterial causes when the diagnosis is not suspected clinically or early in the course. Differences in clinical presentation between the two entities, however, should obviate the need for such imaging in all but the most complicated of cases.

In the acute stage of cervical lymphadenitis where the etiology is not clinically obvious, needle aspiration of the affected node is a valuable diagnostic approach. Of patients with acute cervical lymphadenitis subjected to needle aspiration of the affected node for bacterial and mycobacterial culture, 50% to 88% have an etiologic agent recovered.^{15,26,74,156,185} Only inflamed nodes should be aspirated. The largest or most fluctuant node should be selected, and the skin should be cleansed and anesthetized. Skin anesthesia can be induced effectively using a topical anesthetic cream (e.g., lidocaine-prilocaine [EMLA]) placed on the selected aspiration site under an occlusive dressing 30 to 45 minutes before the procedure. An 18- or 20-gauge needle attached to a 20-mL syringe is used. If no material is aspirated, sterile *nonbacteriostatic* saline 1 to 2 mL is injected into the node and reaspirated. The aspirate should be inoculated directly from the syringe onto aerobic (including chocolate agar) and anaerobic media, onto Sabouraud agar (fungi), and into a broth medium suitable for the early detection of mycobacteria, such as the Bactec radiometric assay. In the latter system, the release of labeled carbon dioxide in an automated ion chamber system can detect mycobacteria 12 to 17 days (and sometimes even sooner) after inoculation of the broth.¹⁵⁷ When mycobacterial infection is suspected, consultation with the laboratory is helpful to ensure that cultures are handled correctly because some species, such as *M. haemophilum*, require that the culture be kept at a temperature of 30°C (86°F) and that heme-containing medium is added for isolation.^{10,151} Gram and acid-fast stains are mandatory and serve as a guide to initial antimicrobial therapy. However, a negative acid-fast stain does not rule out mycobacterial infection, as cultures may still be positive, especially when the etiologic agent is nontuberculous mycobacteria.

PCR assays have successfully confirmed the presence of tuberculous and nontuberculous mycobacteria in gastric aspirates and specimens obtained from lymph nodes by aspiration or biopsy.^{45,51,61,62,149,154} This technique shows great promise in rapidly providing a specific diagnosis.

Thioglycolate broth and anaerobically incubated blood agar plates are incapable of providing optimal conditions for the isolation of many anaerobic bacteria.¹⁵ Optimal methods for cultivation of fastidious anaerobes should be employed because anaerobic organisms may be recovered in 20% of cases.²⁶ Cultures of infected skin lesions and exudates on tonsils also should be done but not to the exclusion of needle aspiration.

Isolation of group A streptococci from the throat or skin cultures of a patient with lymphadenitis does *not* confirm the etiology of the lymph node inflammation. Patients have been noted to have isolation of group A streptococci from throat and of *S. aureus* from lymph node aspirate cultures.^{15,133} Tuberculin skin tests should be performed in children less than 4 years of age, but interferon- γ release assays are more useful in older children.¹⁰ Induration of 15 mm or greater suggests infection with *M. tuberculosis*, whereas reactions of 5 to 14 mm may be caused by either a tuberculous or a nontuberculous mycobacterial infection, because the purified protein derivative preparation shares some antigens with nontuberculous species.^{8,101}

Intradermal skin testing, using a crude extract from affected nodes, historically was used to establish the diagnosis of cat-scratch disease.³¹ A diagnosis usually is reached, however, based on the presence of regional adenopathy, a history of cat exposure (particularly if the patient has a history of a scratch or a primary skin lesion), and negative laboratory studies for other causes of lymphadenopathy. Serologic methods for the detection of immunoglobulin (Ig)G antibodies to *Bartonella* spp. are available^{2,7,189} and should be considered the gold standard for diagnosis. However, sensitivity varies among laboratories. PCR assays are available in some commercial and research laboratories and at the

Centers for Disease Control and Prevention.⁷ In a few cases, a lymph node biopsy should be undertaken to exclude other, more serious pathologies.

If the etiology of adenitis remains uncertain or lymphadenopathy has persisted with no detectable response to antimicrobial therapy, a more intense diagnostic evaluation is indicated. Studies may include a complete blood count; serology for Epstein-Barr virus, cytomegalovirus, HHV-6, HIV, histoplasmosis, coccidioidomycosis, toxoplasmosis, tularemia, *B. henselae*, and *Brucella*; and a radiograph of the chest. If the diagnosis remains in doubt, and the node persists, enlarges, is hard, or is fixed to the adjacent structures, biopsy *should* be performed. Biopsy material should be submitted for the studies outlined earlier for lymph node aspirate cultures and routine histology; Giemsa, periodic acid-Schiff, and methenamine silver stains; and, in select cases only, PCR for viruses and other etiologies. If the histologic examination reveals noncaseating granulomas and the child has a history of cat exposure, the most likely diagnosis is cat-scratch disease.^{100,102} Sarcoidosis involving lymph nodes would have a similar histology but is rare in children and a condition in which isolated cervical node involvement has not been observed.^{73,148}

Older children are more likely to have negative cultures of lymph node aspirates^{15,161} and to be more frequent candidates for excisional lymph node biopsy. They also are more likely to have lymphomas. It is important that appropriate tissue be excised, especially from adolescents, so that precise diagnostic interpretation can be done. This interpretation can be facilitated by the proper selection of a lymph node for a biopsy to be performed; intact removal of the node chosen; and proper fixation, cutting, and staining of the specimen. If only one node or one anatomic group of nodes is enlarged, the largest node should be excised. If several groups of lymph nodes are involved, the site for biopsy should be selected according to the likelihood of diagnostic yield. Biopsy specimens from the lower neck and supraclavicular area have the highest yields.⁷⁶ Other areas, including the upper cervical, submandibular, axillary, and parotid lymph nodes, are much more likely to be affected by reactive hyperplasia, which may or may not be related to the underlying disease process. If lymphoma is suspected, needle biopsies or frozen sections are contraindicated.^{20,28}

Even under optimal conditions, many reactive processes, including rheumatoid arthritis, toxoplasmosis, phenytoin-induced adenopathy, dermatopathic adenitis, and infectious mononucleosis, have been noted to simulate lymphoma.²⁸ Obtaining a thorough history and performing appropriate serologic studies should provide sufficient information for the physician to exclude reactive processes known to simulate lymphoma.

TREATMENT

Optimal management of a child with cervical lymphadenitis depends on an accurate assessment of the underlying etiology. Because almost all cases are associated with infectious agents, every effort should be made to ascertain the etiologic agent so that specific therapy can be initiated. Aspiration of the affected lymph node for Gram and acid-fast stains is a guide for initial therapy, and culture and antimicrobial susceptibility form the basis for prescribing specific treatment in patients with bacterial lymphadenitis.^{15,41} When the patient has findings typical of acute bacterial lymphadenitis, however, empiric therapy may be undertaken without prior needle aspiration. In this situation, close follow-up is essential because failure to show some clinical response after 48 hours of therapy is an indication for further diagnostic procedures to be done.

Acute suppurative cervical lymphadenitis most frequently is caused by infection with *S. aureus* or group A streptococci.^{15,24,41,146,161,186} In nodes that progress to abscess formation, *S. aureus* is the most frequent agent isolated,^{15,41,44,146,182} and drainage is mandatory. Because of the frequency of infection caused by *S. aureus* or group A streptococci, empiric antimicrobial therapy should be directed against these two agents. Penicillinase-resistant penicillins or cephalexin should be used. If the patient requires parenteral therapy and CA-MRSA is uncommon in the geographic area, oxacillin or nafcillin 150 mg/kg per day or cefazolin 75 to 100 mg/kg per day may be used.

When oral therapy is deemed adequate, dicloxacillin 25 mg/kg per day, or cephalexin 25 to 50 mg/kg per day is recommended. The fixed

combination of amoxicillin and clavulanic acid provides good activity against methicillin-susceptible staphylococci and streptococci and has an expanded spectrum of activity against the oral anaerobic organisms. These features, combined with its palatability, render it an attractive alternative to the traditional penicillinase-resistant penicillins. Clavulanate-associated diarrhea can be problematic in some children. In children with mild penicillin allergies, cephalosporins can be used. Ceftriaxone 50 to 100 mg/kg per day is an attractive and effective alternative to the parenteral antibiotics that require more frequent administration if group A streptococcus is the etiologic agent.

In areas where CA-MRSA is prevalent and clindamycin resistance is low, clindamycin 30 to 40 mg/kg per day for parenteral or oral use is appropriate for empiric or alternative therapy. In addition to its good activity against anaerobes and methicillin-susceptible *S. aureus*, clindamycin is effective against most CA-MRSA isolates. However, clindamycin resistance is increasing among community *S. aureus* isolates, so close clinical follow-up to ensure a therapeutic response has been achieved is mandatory when this option is chosen.^{48,68,69,72,115} In a severely ill child needing hospitalization or with signs of deep neck infection (e.g., airway compromise), vancomycin 60 mg/kg per day divided every 6 hours is appropriate in combination with another agent until culture results are obtained. Trimethoprim-sulfamethoxazole 10 mg/kg per day of the trimethoprim component or doxycycline 2 to 4 mg/kg per day if the child is aged 8 years or older are alternative choices for oral therapy of CA-MRSA infections^{48,68,69,115} but should not be used initially because they are not active against group A streptococci. Linezolid is active against MRSA and group A streptococci, but because of concerns regarding cost and bacterial resistance, use should be reserved for cases in which a microbiological need has been confirmed or clinical failure of first-line therapies has occurred. Other parenteral agents active against MRSA and group A streptococci, such as ceftaroline, which is an advanced-generation cephalosporin, are being studied for use in children, but their use cannot be recommended until more pharmacokinetic and efficacy data are available.

Antibiotic therapy may need to be modified if an obvious primary focus of infection suggests a different etiologic agent. In a patient with periodontal or dental disease, adequate anaerobic activity is mandatory, and therapy with penicillin V 50 mg/kg per day, amoxicillin-clavulanate 45 mg/kg per day, or clindamycin 30 to 40 mg/kg per day should be initiated, pending results of cultures.

Patients with marked lymph node enlargement, moderate to severe systemic symptoms, or concomitant cellulitis frequently require parenteral therapy for the first few days. This therapy allows for a high concentration of the antimicrobial agent within the inflamed tissue and may promote more rapid localization, especially in patients with staphylococcal adenitis. Although the use of parenteral drugs has to be individualized, most infants and children with staphylococcal or streptococcal lymphadenitis respond to orally administered antimicrobials.

Adenitis caused by group A streptococci should be treated with penicillin G 100,000 to 150,000 IU/kg per day or penicillin V 50 mg/kg per day for a total of 10 days. In a child with penicillin allergy, azithromycin 10 mg/kg per day on day 1, then 5 mg/kg per day on days 2 through 5, or cephalexin 25 to 50 mg/kg per day can be used. These drugs have been shown effective in the treatment of cervical lymphadenitis.^{15,24} Treatment should be continued for at least 10 days or approximately 5 days after signs of local inflammation and systemic toxicity have disappeared, whichever is longer. If required, analgesics should be given and not overlooked in infants and children too young to verbalize their discomfort. The average duration of antibiotic therapy is 10 days, unless abscess formation occurs late in the first or early in the second week of treatment.¹⁵ In this situation, incision and drainage is indicated,^{15,25,41} and therapy should be continued until resolution of the acute process occurs, usually within another 5 to 7 days.

Some clinical improvement is to be expected within 48 hours after initiation of therapy and is manifested by a decrease in inflammation and tenderness of the lymph node and a decrease in the maximum daily temperature. The size of the lymph node may not show evidence of regression at this stage, and total resolution of fever should not be expected. It is important to record accurate measurements of the node at the time of presentation because a subjective evaluation is an unreliable

indicator of lymph node evolution during therapy. If no clinical improvement is noted by 48 hours, needle aspiration is recommended. The history and physical examination should be reassessed, and a more detailed laboratory evaluation should be initiated.

In a study of 284 children admitted to the hospital with acute cervical adenitis, age younger than 1 year and node involvement for more than 48 hours before admission predicted the need for node aspiration.⁹⁶ Regression of the size of a lymph node is slow, usually requiring 4 to 6 weeks or more. Persistence of significant enlargement beyond 6 to 8 weeks, even in the face of good initial response to antimicrobial therapy, demands that an underlying disorder be excluded. When signs of acute inflammation have resolved, prolonged antimicrobial therapy is of little value because penetration of antimicrobials through the fibrous capsule of the node is poor.²⁴ Spontaneous regression occurs in most patients, although it may require several weeks. Uncommonly, reactivation of inflammation may occur, and a meticulous search for an untreated primary source of bacterial infection, such as secondarily infected dermatitis, infestation, foreign body, or dental abscess, should be undertaken. Retreatment should include specific measures to eliminate the predisposing condition.

If Gram stain of the lymph node aspirate suggests a microorganism other than *S. aureus* or group A streptococci, initial antimicrobial therapy should include therapy for the most likely agents until culture results are known. Because attempts to perform careful Gram stains and anaerobic cultures of lymph node aspirates in most reported series have been limited, the large number of infants and children with sterile aspirates may be attributed partly to a failure to isolate fastidious anaerobes indigenous to the mouth. These microorganisms should respond to penicillin G therapy. For penicillin-resistant organisms, clindamycin is a useful alternative drug.

For infants in the first 2 months of life, group B streptococci and *S. aureus* are important pathogens to consider in selecting initial therapy. Penicillinase-resistant penicillins are active against both agents, unless the occurrence of CA-MRSA is frequent, in which case clindamycin or vancomycin should be considered for initial therapy. If group B streptococci are isolated, penicillin G can be substituted. Final bacteriologic identification and antimicrobial susceptibility tests should be the ultimate guide to selecting specific antimicrobial therapy in all patients. Treatment of cervical lymph node infections associated with rarely encountered bacteria, fungi, and parasites listed in Table 12.3 is discussed under those specific disease entities.

Although controversy exists as to whether cervical adenitis associated with *M. tuberculosis* in a child is truly a localized process, only rarely do patients have disseminated infection.^{42,60,121} When infection is not localized, pulmonary or hilar lymph node involvement is a common finding.^{10,42,74,122} A 2-month regimen of isoniazid 10 mg/kg per day, rifampin 10 to 20 mg/kg per day, pyrazinamide 30 mg/kg per day, and ethambutol 20 mg/kg per day is recommended for the treatment of uncomplicated pulmonary tuberculosis or isolated cervical lymphadenitis in children. This therapy is given for 2 months, daily for at least the first 2 weeks, and then 2 to 3 times per week, after which isoniazid and rifampin are administered 2 to 3 times per week for the ensuing 4 months. Twice weekly therapy is not recommended for HIV-infected people.¹⁰

In areas where multidrug resistance in *M. tuberculosis* is prevalent, streptomycin 20 to 40 mg/kg per day or another aminoglycoside (kanamycin, amikacin, or capreomycin) is added for initial treatment until drug susceptibilities are known.^{10,34,35} The addition of a fifth drug should occur after consultation with an expert in the field because these drugs may have toxic effects, and careful assessment of the risks and benefits is warranted. Detailed discussion of the treatment of tuberculosis in children is provided in Chapter 96. Response to antituberculous therapy is usual, with rapid resolution of symptoms and marked regression of lymph nodes within 3 months. Nodes remain palpable for months, however, because scarring and fibrosis are regular accompaniments to resolution of disease. Draining sinuses, a common complication of lymph node aspiration or incision, and drainage before the advent of effective antituberculosis chemotherapy no longer develop.

Cervical lymphadenitis attributed to nontuberculous mycobacteria is much more common in a young child than that caused by *M.*

tuberculosis. These microorganisms exhibit in vitro resistance to commonly employed antituberculosis drugs. Resistance particularly is common among *M. scrofulaceum* and *M. intracellulare*. Surgical excision remains the treatment of choice for nontuberculous mycobacterial lymphadenitis, and total removal of all the visibly affected nodes is recommended.* Early (within 1 month of onset) removal of affected nodes was associated significantly with better aesthetic results.⁹⁸ Thorough curettage has been found effective^{88,99,121} but results in delayed healing, higher relapse rates, and less favorable aesthetic result.^{49,88,190}

Antimicrobial therapy alone is less effective.^{89,105,190} The macrolides clarithromycin and azithromycin, rifampin and its analogue rifabutin, ethambutol, amikacin, and cefoxitin show activity against nontuberculous mycobacteria.^{8,59,163} Retrospective case series with small cohorts of patients showed that clarithromycin monotherapy and combination therapy with clarithromycin and ethambutol or rifampin (or rifabutin) had some success in the treatment of nontuberculous lymphadenitis and a relatively low rate of recurrence.^{19,58,67,94,95,99,165} The regimens used generally were well tolerated. Rifabutin resulted in adverse effects in four of seven patients treated for 6 months in one study (neutropenia and yellow skin pigmentation), which disappeared after dose reduction.⁹⁴ In HIV-infected children receiving protease inhibitors, rifabutin generally is contraindicated, but it can be given at a much reduced dosage if deemed necessary.⁸

In one randomized controlled clinical trial, 100 children (median age, 45.5 months; range, 9 to 168 months) with microbiologically proven nontuberculous lymphadenitis received either surgical resection or clarithromycin 15 mg/kg per day and rifabutin 5 mg/kg per day orally for 12 weeks.⁸⁹ There was a 30% higher cure rate (96% vs. 66%) for patients treated surgically in contrast to those who received antibiotics alone. The cure rate was not influenced by lymph node stage of infection or infecting mycobacterial species. Postoperative wound infection and facial nerve weakness occurred in 12% and 14% of children, respectively, and, in one child, facial nerve weakness was permanent. In the two patients in whom surgical resection was not curative, the lesions responded to 3 months of the antibiotic regimen. In a follow-up study of this cohort 1 year later, aesthetic outcome also was significantly better in the surgical group.⁹¹ In another study of 50 patients with advanced nontuberculous mycobacterial adenitis who received either the previously mentioned antibiotic regimen or no treatment, the median time to resolution was only 4 weeks earlier (36 vs. 40 weeks) in the treated group.⁸⁷

Zimmermann and associates recently performed a meta-analysis of 60 publications in children with cervical lymphadenitis caused by nontuberculous mycobacteria and found an adjusted cure rate of 98% for complete surgical excision versus 73.1% for medical therapy and 70.4% for no intervention.¹⁹⁰ Complete excision was associated with a 10% risk of facial palsy, and 2% of cases had permanent palsy. The authors conclude that the decision to perform complete excision should be dependent on location. Regarding medical therapy, studies to date suggest that regimens of a macrolide (clarithromycin or azithromycin) plus either ethambutol and/or rifampin (or rifabutin) are options for the treatment of nontuberculous mycobacterial adenitis for which complete excision of the affected node would endanger the facial nerve or its branches if a reduction in size of the swelling would facilitate a complete and aesthetic excision at a later stage, for recurrent disease or if surgery is refused.⁸ Macrolide monotherapy is not recommended because of the risk for inducing resistant organisms. The optimal duration of therapy is unknown, but regimens of 4 to 6 months or longer are usual. Expert opinion should be sought, especially as new mycobacterial species are described.⁸

Cat-scratch disease usually is a benign, self-limited disorder requiring no specific therapy, but the use of antimicrobials may relieve symptoms and hasten recovery. Rifampin, azithromycin, trimethoprim-sulfamethoxazole, doxycycline, ciprofloxacin (the latter two agents in older children), and parenteral gentamicin may be useful in promoting fever defervescence and in clinical resolution of systemic cat-scratch disease.^{7,11,16,104} If the lymph node progresses to fluctuance, needle aspiration may hasten resolution and relieve discomfort. Surgical excision may be required in a few patients who have persistent problems despite having needle aspiration or who develop draining sinuses.

*References 5, 8, 33, 47, 65, 88, 89, 103, 119, 127, 135, 143, 156, 178, 190.

PROGNOSIS

With effective antimicrobial therapy, complete resolution of cervical lymphadenitis caused by *S. aureus*, group A streptococci, and *M. tuberculosis* is the rule. Delay in establishing the diagnosis or initiating therapy can prolong the clinical course and result in complications or sequelae, such as sinus tracts (mycobacteria),^{21,36,122} abscess formation,^{25,44} cellulitis or bacteremia (*S. aureus* and *S. pyogenes*),¹⁵ acute glomerulonephritis (group A streptococci),⁴⁰ disseminated disease (*M. tuberculosis*),⁷⁴ or mycotic carotid artery aneurysm.¹⁷⁷ Except for abscess formation, these complications are rare events. Although lymph node infection caused by *S. aureus* is more likely to result in abscess formation, at least one study has noted a significantly greater duration of infection before treatment in patients in whom *S. aureus* was isolated from the abscess cavity cultures.¹⁵ The extracellular products of this organism (e.g., coagulase, fibrinolysin, and hyaluronidase) partly explain its propensity for abscess formation, which occurs in 50% to 70% of patients.^{25,41}

Even in patients whose course is complicated by suppuration, appropriate drainage in conjunction with specific antimicrobial therapy results in prompt resolution of signs and symptoms, and relapse occurs only rarely. Today, surgical excision of affected nodes seldom is recommended except when the disease is caused by nontuberculous mycobacteria, in which case surgical excision remains the treatment of choice.¹⁹⁰ Antimicrobial therapy has been responsible for the disappearance of the events commonly associated with cervical adenitis historically, including thrombosis of the internal jugular vein, rupture of the carotid artery, generalized septic embolic phenomena, mediastinal abscess, purulent pericarditis, and even death.^{78,160}

With the advent of effective antituberculous agents, the prognosis for tuberculous cervical adenitis also is excellent. When surgical excision is performed early in the course of lymphadenitis caused by nontuberculous mycobacterial infection, resolution can be anticipated.^{49,98,127,135,143,155,190} Persistent and recurrent disease is the most frequent complication encountered.¹⁷⁸ Macrolide monotherapy and combination therapy are useful in ameliorating these complications or in cases for which surgery is not feasible.^{8,129,155} Cat-scratch disease usually is a benign, self-limited disorder in which therapeutic intervention, such as needle aspiration to relieve pain, is uncommonly needed, but antibiotic therapy can hasten recovery.

PREVENTION

Providing appropriate medical and, occasionally, surgical therapy of predisposing conditions (e.g., dental caries, abscess, group A streptococcal pharyngitis or nasopharyngitis, purulent otitis media, impetigo, other infections involving the face and scalp) and minimizing the exposure of infants and children to adults with active tuberculosis should reduce the incidence of cervical lymphadenitis. Some authors suggest that decreased exposure to animals may result in fewer infections,¹⁶ especially for adenitis attributed to toxoplasmosis or *Bartonella*.^{32,136}

Parotitis, inflammation of the parotid gland, is caused by a variety of infectious agents and noninfectious systemic illnesses. Several terms are used to describe the clinical presentations and etiologic processes that lead to parotid gland swelling and inflammation. *Suppurative parotitis*, first described in the 1800s, is a serious bacterial infection in neonates and postsurgical patients.⁵¹ *Epidemic parotitis*, particularly prevalent in the prevaccine era, was caused primarily by mumps virus infection.⁵⁸ In the postvaccine era, this form of parotitis also is caused by other viral pathogens and is referred to as *viral parotitis*. Rarely a more indolent, slowly progressive, granulomatous infection may occur that is referred to as *granulomatous parotitis*. *Recurrent parotitis of childhood* is a unique illness characterized by multiple episodes of acute and subacute parotid gland swelling. The histologic findings in this disease include architectural changes in the ducts and chronic inflammation. Many noninfectious systemic illnesses cause persistent or recurrent parotid gland swelling and inflammation, which is referred to as *chronic parotitis*. Bilateral parotid enlargement is a frequent presentation of human immunodeficiency virus (HIV) infection as part of the *diffuse infiltrative lymphocytosis syndrome*.

PATHOPHYSIOLOGY

Despite the various agents that cause parotitis, involvement of the gland occurs mainly by three mechanisms. The most common mechanism is a localized infection limited to the gland and surrounding structures. Parotitis may be a manifestation of a systemic infection, as in mumps, or rarely may develop secondary to hematogenous seeding during periods of transient bacteremia. Several common contributing factors and pathophysiologic mechanisms lead to swelling of the gland. The parotid is well encapsulated and consists of superficial and deep lobes separated by the facial nerve. The parotid duct (Stensen duct) traverses the buccal soft tissue anteriorly and exits opposite the second upper molar. Thin, watery secretions from the parotid gland cleanse the ductal system and have some bacteriostatic properties, preventing accumulation of bacteria and debris.³⁸ Factors that predispose individuals to the development of parotitis include side effects of certain drugs and diseases that lead to dehydration, xerostomia, or ductal obstruction (Box 13.1).^{38,51} Decreased salivary flow allows retrograde migration of bacteria. Stasis in the ductal system, caused by ductal ectasia, inflammation, calculi, or strictures, allows proliferation of bacteria and inflammation within the gland.

ETIOLOGY

Infectious parotitis may be caused by aerobes, anaerobes, mycobacteria, and viruses (Box 13.2). In all age groups, *Staphylococcus aureus* is the organism most commonly associated with suppurative parotitis.^{49,51} Gram-negative pathogens (e.g., *Escherichia coli* and *Klebsiella* and *Pseudomonas* spp.) also may cause suppurative parotitis, particularly in neonates and debilitated or hospitalized patients.^{12,33,50,51} The role of anaerobic organisms in this infection has become apparent, especially when poor oral hygiene and oral pathology are associated features.^{4,5,41} In cases of recurrent parotitis of childhood, *Streptococcus* spp. are the bacteria most commonly isolated.^{23,44,48} Granulomatous parotitis most often is caused by *Mycobacterium tuberculosis* and may occur in the absence of systemic or disseminated tuberculous disease.^{38,46,54} Other causes of granulomatous parotitis include *Mycobacterium avium-intracellulare*, *Actinomyces* spp., and gram-negative intracellular organisms (*Francisella tularensis* and *Brucella* spp.).^{27,38,61}

In the postvaccine era, the most common viral cause of parotitis still is the paramyxovirus mumps virus. coxsackieviruses, Epstein-Barr virus, influenza A virus, parainfluenza viruses, adenovirus, human herpesvirus-6, herpes simplex virus, cytomegalovirus, and lymphocytic choriomeningitis virus all have been implicated in cases of parotitis.^{1,2,17,30,32,34,37,38}

CLINICAL PRESENTATION AND DIAGNOSIS

A detailed history and physical examination are crucial in assisting the clinician in determining the most likely etiology of parotid gland swelling. One should determine the onset and duration of symptoms, their periodicity, and the character of salivary secretions. In addition, the presence of a systemic disease must be excluded. Examination of the parotid gland is achieved best by simultaneous palpation of the intraoral and extraoral salivary structures. Gentle external pressure should be applied to the gland, and the parotid duct should be examined for evidence of purulent secretions or surrounding erythema.

Suppurative parotitis occurs most commonly in neonates or patients with dehydration, poor oral hygiene, malnutrition, immunosuppression, oral trauma, sepsis, or any medication or disease that decreases salivary secretions.²⁰ Usually, the disease is unilateral; however, bilateral suppurative parotitis may occur in 17% of cases.⁴⁴ The disease is characterized by acute onset of pain, swelling, warmth, and induration of the involved gland and purulent discharge from the Stensen duct. Associated physical findings include fever, trismus, malaise, and cervical adenitis. In suppurative parotitis, Gram stain and culture (aerobic and anaerobic) of purulent material from the duct can provide a specific microbiologic diagnosis. In addition, elevation of the white blood cell count with a neutrophil predominance may help differentiate this form of parotitis from viral parotitis and parotid disease of a noninfectious etiology.

Mumps is the most common form of viral parotitis and is characterized by a prodrome of fever, malaise, anorexia, and headache. Usually, the following day, unilateral or bilateral earache and parotid tenderness develop. The gland or glands enlarge during the subsequent 2 to 3 days, and the orifice of the Stensen duct is erythematous and swollen, yet secretions from the duct are clear. At the point of maximal swelling, the angle of the jaw is obliterated and the earlobe is lifted upward and outward. The other salivary glands are involved in 10% of cases.⁴⁴ Rare systemic manifestations of mumps infection include epididymo-orchitis, meningitis, meningoencephalitis, and oophoritis. More recent outbreaks of confirmed and probable mumps emphasize that this infection may occur in highly immunized populations.^{6,18} In 2006, the United States had the largest mumps epidemic in two decades, involving more than 6000 patients. Most cases occurred in Midwestern states (Iowa, Kansas, Wisconsin, Illinois, Nebraska, and South Dakota). The highest incidence was among college-aged students, most of whom had received two doses of measles-mumps-rubella (MMR) vaccine.^{6,18} The largest U.S. mumps outbreak since 2006 began at a summer camp in New York in June 2009. This outbreak included 1521 cases. Vaccination status was known for 1115, of which 976 (88%) had received at least one dose of mumps-containing vaccine.⁷ Other viral agents may produce similar clinical manifestations and can be differentiated from mumps only by culture and hemagglutination inhibition, complement fixation, or enzyme-linked immunosorbent assay serology.¹⁷ In viral parotitis, the white blood cell count may be normal, slightly elevated, or depressed, with a lymphocytic predominance.

Granulomatous parotitis typically manifests as a painless, slowly enlarging mass without surrounding inflammation. It may be

misdiagnosed as a slow-growing tumor until the correct diagnosis is made by biopsy and culture. *M. tuberculosis* and *M. avium-intracellulare* may cause infection in the parenchyma of the gland or in intraglandular or periglandular lymph nodes.^{45,61} Clinical evidence of systemic tuberculous disease usually is absent. Parotitis has been observed as an extension of nontuberculous cervical adenitis.⁶¹ Actinomycosis of the parotid gland causes a slowly enlarging, nodular, nontender gland; associated oral or cervicofacial infection usually is present. Fistulas draining yellow or white material with sulfur granules are common findings.²⁷

Recurrent parotitis of childhood is rare, with onset typically occurring before the child reaches 10 years of age and a peak incidence at approximately 6 years of age.^{19,44} Some authors hypothesize that an underlying congenital abnormality, such as sialectasis, is a common predisposing feature.^{35,45} Others suggest that selective IgA deficiency may be a contributing variable.²¹ Clinically, these children experience repeated episodes of fever, pain, and unilateral swelling of the parotid gland. Purulent material can be expressed from the Stensen duct and, when cultured, often yields streptococcal organisms. Sialography and ultrasound reveal multiple areas of sialectasis throughout the parotid glands bilaterally, even if only one side is symptomatic. The frequency of attacks varies, and each episode of parotitis may last 2 weeks, when it resolves spontaneously.¹¹ Several authors have noted that recurrences become less frequent with increasing age and that the disease tends to cease at the onset of puberty or early adulthood.^{19,44}

HUMAN IMMUNODEFICIENCY VIRUS AND PAROTID ENLARGEMENT

Salivary gland enlargement has been recognized as a common finding in children infected with HIV since before the era of highly active antiretroviral therapy (HAART).³⁶ The prevalence of this manifestation in HIV-infected individuals is 0% to 58%.⁴⁸ More recently, in a retrospective report of oral lesions in a cohort of HIV-infected children from Brazil, Miziara and colleagues⁴² noted the prevalence of parotid gland enlargement to be 7.6%. Although parotid enlargement occurred more commonly in children older than 5 years of age, the prevalence did not differ between children who were receiving antiretroviral therapy without protease inhibitors and children who were receiving HAART.

The exact pathophysiology is unknown, but proposed mechanisms include lymphoepithelial cysts, lymph node enlargement within the gland, cytomegalovirus or Epstein-Barr virus infection, and diffuse infiltrative lymphocytosis syndrome of the gland.⁴⁸ This entity in

HIV-positive children possibly is associated with the HLA-DR5 and HLA-DR11 phenotypes, but the significance of this finding is unclear.^{29,48,57} Bilateral parotid enlargement frequently is seen as part of diffuse infiltrative lymphocytosis syndrome, which is characterized by proliferation of CD8⁺ lymphocytes within the circulation and is of unclear etiology. Growth of the parotid is secondary to infiltration of CD8 lymphocytes into the gland, follicular hyperplasia of intraparotid lymphoid tissue (as occurs in lymph nodes throughout the body in HIV infection), and development of diffuse intraparotid, lymphoepithelial cysts.^{9,39} Epstein-Barr virus has been proposed as an impetus for CD8 lymphoproliferation because the virus has been isolated from parotid tissue of some affected patients.¹⁰ The absence of positive serology for the virus renders it an unlikely causative agent, however. HIV, which may be the inciting agent, has been detected in dendritic cells, macrophages, and lymphocytes isolated from the parotid glands of affected patients.¹⁰

Parotid enlargement may be present in 20% to 50% of children with HIV infection and acquired immunodeficiency syndrome (AIDS).^{31,35,56,59} The median time from birth to development of parotid enlargement is 4.6 years, and often it is the first manifestation of HIV infection acquired during the perinatal period in an otherwise healthy older child.^{29,31,36} HIV-positive children with enlarged parotid glands tend to have a slower progression to death than do HIV-positive children with

oral herpes or candidiasis.³¹ Usually, both parotid glands are involved, and an affected patient presents with enlarged, tender parotid glands, xerostomia, and increased serum amylase level.⁸ Severity of pain and size of the gland tend to fluctuate without apparent cause. This manifestation of HIV infection and AIDS is still commonly seen in developing countries where access to antiretroviral therapy is limited.

The differential diagnoses for parotid enlargement in an HIV-positive patient include viral and bacterial parotitis. Some patients have preexisting xerostomia that may increase their susceptibility to parotitis. In addition, the immunocompromised state of patients with AIDS may predispose them to development of infection of the parotid gland with other agents, such as cytomegalovirus, Epstein-Barr virus, bacteria, mycobacteria, and fungi.^{25,53,60,63} Noninfectious etiologies, such as non-Hodgkin lymphoma or Kaposi sarcoma, also should be included in the differential diagnosis of parotid gland enlargement in an HIV-infected patient, although these manifestations usually are observed in adults.

DIFFERENTIAL DIAGNOSIS

Parotitis most often is diagnosed based on clinical presentation, microbiology, serology, and response to empiric therapy. Ultrasound may be useful as a screening tool to prompt more sensitive modalities if the ultrasound scan is abnormal.⁴³ Computed tomography is most useful in the presence of anatomic defects, radiolucent calculi, or abscess formation in the parotid gland.⁵² X-ray sialography is the gold standard in examining the parotid gland ducts; however, sialography is contraindicated in the setting of acute infection. Magnetic resonance sialography is a promising alternative and has several advantages. In contrast to x-ray sialography, magnetic resonance sialography is not contraindicated during acute parotitis and does not require injection of contrast material or involve manipulation of the Stensen duct.²² Nonetheless, experience with magnetic resonance sialography is limited, and this mode alone may not be sufficiently sensitive to detect tertiary salivary ductules or calculous disease.^{22,64}

Noninfectious causes of parotid swelling and inflammation include collagen vascular diseases (Sjögren syndrome and systemic lupus erythematosus), metabolic disorders (hepatic disease, hyperlipoproteinemia, and hyperuricemia), endocrine disorders (diabetes mellitus and hypothyroidism), tumors, leukemic infiltration, drugs (antineoplastic chemotherapy), and poisons (iodine).^{38,44,49} Sjögren syndrome, the most common cause of noninfectious parotitis, is caused by lymphocyte-mediated destruction of the exocrine glands.^{26,49} Patients with this disease have diminished or absent glandular secretions and mucosal dryness; xerostomia and keratoconjunctivitis sicca are prominent clinical features. In addition, the parotid glands are enlarged bilaterally, are firm, and have an irregular contour. Sialography reveals sialectasia, and saliva from these patients has unique biochemical characteristics. Antibodies to nuclear antigens SS-A and SS-B can be detected in the sera of patients with Sjögren syndrome.⁴⁹ Patients with chronic noninfectious parotitis have changes in the ductular architecture or strictures that can predispose them to episodes of infectious parotitis.

TREATMENT

Treatment of parotitis includes rehydration, parotid massage, discontinuation of any medications that diminish salivary flow, and sialogogues (e.g., lemon drops, hard candy, and chewing gum), which increase salivary flow.^{3,38,49,51} In cases of suspected suppurative parotitis, a broad-spectrum antibiotic regimen that is effective against *S. aureus*, *Streptococcus* spp., gram-negative organisms, and anaerobes should be administered empirically, pending specific culture results. Antibiotic regimens frequently employed include penicillinase-resistant penicillins, first-generation cephalosporins, and clindamycin in combination with an

aminoglycoside.³ Vancomycin should be used if methicillin-resistant *S. aureus* (MRSA) is the likely pathogen. If the patient has been hospitalized for a prolonged period, or if the predominant organisms on Gram stain of the purulent discharge are gram-negative, ceftazidime should be considered as initial empiric therapy.^{49,51}

Surgical incision and drainage of purulent fluid are indicated if there is slow or no response to medical therapy or if fluctuance increases.⁵⁵ The treatment of viral parotitis consists of antipyretics, analgesia, and hydration. In cases of mycobacterial infection, excision of the gland may be required, in addition to administration of specific antimycobacterial therapy.^{46,54} Reports have described successful treatment with clarithromycin and azithromycin of parotitis caused by atypical mycobacteria.²⁴ In contrast, actinomycosis of the parotid gland is managed medically with penicillin G.²⁷ Children with recurrent parotitis should be treated with antibiotics during acute episodes, but chronic suppressive antimicrobial therapy is not recommended.

Tympanic neurectomy involves severing the parasympathetic secretomotor fibers of the tympanic plexus to the parotid. This procedure attenuates secretion from the gland and relieves sialectasia and further episodes of parotitis in more than 70% of patients.^{16,47} Only 10% to 20% of these patients require parotidectomy for persistence of symptoms beyond puberty.¹⁴ Although it is the optimal treatment for complete resolution of recurrent parotitis, parotidectomy carries a risk for facial nerve injury. Nahlieli and colleagues⁴⁵ described the use of endoscopy to diagnose and endoscopic irrigation to treat children with recurrent parotitis.

COMPLICATIONS

With improved fluid management of postsurgical patients and the use of broad-spectrum antimicrobial agents, complications secondary to infectious parotitis now are rare events. In neonates or immunocompromised patients, sepsis may be a severe complication of this infection. Abscess formation may result from delayed or ineffective therapy. Compromise of the facial nerve may occur and can resolve with successful treatment of the infected gland.⁴⁰ The most serious and rare complication is extension to other structures of the head and neck and along fascial planes to the face, external auditory canal, jugular vein, mandible, and mediastinum.

PREVENTION

Suppurative parotitis can be prevented in postsurgical patients by maintaining adequate hydration and good oral hygiene. The most common form of viral parotitis, mumps, can be prevented by appropriate vaccination. Between 1968 and 1993, a 99% reduction in the incidence of new cases of mumps occurred.⁶² In the mid-1980s and more recently in 2006, a resurgence of the incidence of mumps in previously vaccinated populations was noted.^{6,13,18,28} The most recent outbreaks occurred among college students and young adults in several states, raising concern of waning immunity in this highly vaccinated population.^{6,18} The current recommendation is to provide two doses of live mumps vaccine for school-age children (i.e., grades kindergarten through 12) with MMR vaccine and to ensure that students in college or other post-high school educational institutions also have received two doses of MMR vaccine.^{6,15,18}

Rhinosinusitis (commonly referred to as “sinusitis”) is inflammation of the mucosal lining of one or more of the paranasal sinuses. Although inflammation of sinus mucosa most probably occurs to some degree with every upper respiratory tract infection that produces rhinitis, most of these episodes apparently have a spontaneous resolution.¹⁰⁶ Studies during the past 3 decades estimate that 5% to 10% of upper respiratory tract infections are complicated by acute sinusitis.^{2,207,228} This rate range represents a significant increase from earlier reports,⁴⁵ possibly because of a greater awareness of the illness and improved imaging techniques. The growing number of children in daycare has led to an actual increase in the incidence of upper respiratory tract infections.^{226,228} In addition, recognition that sinus infection can have a negative effect on the health of children with chronic pulmonary disease has increased interest in this disease.¹²³

When considering a diagnosis of sinusitis in a child, the major problem is to distinguish simple upper respiratory tract infection or allergic inflammation from secondary bacterial infection of the sinuses.^{151,181} Unless complications such as periorbital cellulitis or cavernous sinus thrombosis render the diagnosis obvious, the clinician has no reliable way to establish a diagnosis of acute sinusitis in the office setting. Sometimes symptoms and signs of sinusitis occur simultaneously with rhinitis, but most often they occur after an episode of rhinitis. Infection in the sinuses usually persists after the preceding rhinitis has resolved. Sinusitis is classified by the duration of clinical symptoms: acute (≤ 3 weeks), subacute (3 to 12 weeks), and chronic (>12 weeks). Available data comparing acute and subacute sinusitis are sparse; both entities may have a similar etiology, diagnosis, and prognosis; the distinction seems to be arbitrary and to have no clinical significance.

HISTORY

Purulent sinusitis and its relationship to orbital inflammation have been known for more than 2000 years.⁸⁰ Highmore, a 17th-century English physician and anatomist, is given credit for the separation of dental and antral disease.¹⁵⁶ Hunter indicated the importance of surgical drainage in purulent sinusitis and suggested perforating the partition between the maxillary antrum and the nose.¹⁵⁶ During the first half of the 20th century, sinusitis was responsible for considerable morbidity and mortality, and surgical care of sinusitis frequently was lifesaving. Since the advent of antibiotics, sinusitis has had a lower medical profile. Interest in this topic has increased, however. Some factors involved in this increased interest include the advent of the newer surgical techniques of functional endoscopic sinus surgery that yield comparable results to sinus puncture and aspiration,²⁰⁴ which now have been applied to children; improved diagnostic imaging studies, especially thin-cut computed tomography (CT) imaging; and the greater social importance of upper respiratory tract infections for parents who must be absent from work to seek treatment for their children.¹²³

ANATOMY

All the paranasal sinuses develop as outpouchings of the nasal cavity. Three shelflike structures—the inferior, middle, and superior turbinates—are on the lateral nasal wall. The superior turbinate is not well developed in the first year of life.²⁴⁰ Beneath each turbinate is the corresponding meatus into which various drainage pathways open. Specifically, the nasolacrimal duct drains tears into the inferior meatus; the frontal, maxillary, and anterior ethmoidal sinuses drain into the middle meatus; and the sphenoidal and posterior ethmoidal cells open high in the nasal vault in the proximity of the superior meatus.²¹⁶

The maxillary sinuses develop early in the second trimester of fetal life as lateral outpouchings in the posterior aspect of the middle meatus. They are present at birth,^{7,131,174,240} with floors being barely below the attachment of the inferior turbinates.²¹⁶ They expand rapidly by the time the child is 4 years of age.²⁴⁰ Ultimately, at full size, the lateral borders of the maxillary sinuses reach the lateral orbital rims. The position of the floors of the sinuses is determined by the eruption of the dentition.²¹⁶ The ostia of the maxillary sinuses are located high on the medial walls of the sinuses, which impedes gravitational drainage of secretions; ciliary activity is required to move secretions from the body of the maxillary sinuses through the ostia into the nose.²¹⁶

The ethmoidal sinuses develop in the fourth month of gestation²¹⁶ and are present at birth.^{131,174,240} They are not a single large cavity but a grouping of cells, three to 15 in number, each with its own opening or ostium. They have a honeycombed radiographic appearance and are small anteriorly and large posteriorly. The walls of the ethmoidal labyrinth, especially the lateral walls bordering on the orbits (and forming its medial walls), are thin and referred to as the *lamina papyracea*.²¹⁶

Development of the frontal sinuses is variable. In adults, 80% have bilateral frontal sinuses, 1% to 4% have agenesis of the frontal sinuses, and the remainder have unilateral hypoplasia. The position of the frontal sinuses is supraorbital after the child reaches 4 years of age, but they are not distinguished radiographically from the ethmoidal sinuses until the child is 6 to 8 years old. The frontal sinuses do not reach adult size for another 8 to 10 years.²¹⁶

The onset of development of the sphenoidal sinuses occurs during the child's first 2 years of life, but they remain rudimentary until the child is approximately 6 years of age. They have reached their permanent size, although not their permanent shape, by the time the child is 12 years old.²⁴⁰

Although the full development of the sinuses may take 20 years, by the time the child is 12 years old the nasal cavity and the paranasal sinuses have nearly completed their development and have reached adult proportions.²⁴⁰ Sinus disease in postpubertal adolescents is similar to that in adults.

The mucosal lining of all the paranasal sinuses is composed of ciliated columnar epithelium and goblet cells.¹⁷⁷ It is continuous and similar to the lining of the nasal cavity except that the mucosa in the nose is thicker and contains more glands. The epithelium of all the paranasal sinuses and nasal cavity is covered in part by a blanket of mucus.

PATHOPHYSIOLOGY

The pathogenesis of sinus infection undoubtedly is similar to that of otitis media.²²² The middle ear, with its extension, the eustachian tube, and the paranasal sinuses normally are sterile, but their contiguous areas (nasopharynx and nose) have a dynamic microbial flora. Under normal conditions, ciliary function with mucus flow can be expected to keep the sinuses clear of pathogens. The cilia within the sinuses propel the mucus toward their respective ostia and, from there, nasociliary action moves the mucus blanket posteriorly toward the pharynx. Insults that damage the ciliary epithelium and affect the morphology, number, and function of cilia and insults that alter the production or viscosity of the mucus blanket lead to obstruction of the flow of mucus, however, which allows the inoculation of numerous microorganisms into the sinuses that can lead to infection. In a study in adults in whom sneezing, coughing, and nose blowing were stimulated or initiated voluntarily, intranasal pressures were measured, and the deposition of contrast medium (which before the initiation of the event had been inoculated into the nasopharynx) was determined by CT.⁷⁴ Results of this study

showed that nose blowing introduced viscous fluid into the maxillary sinuses, whereas coughing or sneezing did not generate enough pressure to propel fluid into the sinuses. When instituted, sinus infection is complicated further by inflammatory obstruction of the ostium leading to the nose.

The most important factor leading to purulent sinus infection in children and in adults is upper respiratory tract viral infection.^{24,52,123,228} Wald and colleagues²²⁸ in a large prospective study involving children younger than 3 years of age showed a doubling of the rate of sinusitis (defined as upper respiratory tract symptoms persisting >15 days) among children in a daycare setting compared with children not in daycare. The differences presumably were due to increased exposure to viral respiratory illnesses. Radiographic studies in children with acute colds regularly indicate abnormalities of the maxillary sinuses, suggesting that the infection involves these areas.¹²⁶ These asymptomatic sinus opacifications may persist for 2 weeks after the symptoms of the upper respiratory tract illness have resolved.^{49,104,216} Viral infection that involves the sinuses rarely is differentiated from its primary manifestations, such as the common cold, nasopharyngitis, and influenza, and recovery is the rule. If the effect of the viral infection on the mucosal surface is severe and is associated with the inoculation of one or more pathogenic bacterial agents and obstruction of an ostium, disease occurs.

The mechanisms by which upper respiratory tract viral infections set the stage for secondary bacterial infection in the sinuses are complex. Using *in situ* hybridization, rhinovirus RNA was shown inside epithelial cells of maxillary sinus in 50% of a small number of adults with acute sinusitis.¹⁵³ This finding is remarkable because in experimental rhinovirus infections, only a small percentage of nasal epithelial cells were noted to contain rhinovirus RNA.⁸ These differences may reflect only differences in inoculum between experimental and natural infection, but they may indicate heavier infection in the sinuses than in the nose. Symptoms in upper respiratory tract viral infections are not caused by extensive damage to ciliated nasal epithelium but rather to aspects of the host response (see Chapter 7).^{8,75,138,140,149,157,158,239}

Other irritants can set the stage for sinus infection. Swimming in ocean, lake, or chlorinated pool water can lead to sinus involvement. Drying of the nasal mucosa, which occurs commonly during the winter in cold climates, may be a precipitating factor.

Dental infections or extractions also can lead to maxillary sinusitis if the tooth root is adjacent to, or sometimes penetrating, the maxillary sinus floor.³⁹ Sudden change in pressure, as with diving or during descent in an airplane, physically can overcome local mucociliary defense mechanisms and lead to the sudden onset of acute sinusitis.¹³⁷

A number of host factors and perhaps microbiologic factors are associated with recurrent and chronic sinusitis.*

Recurrent chronic sinusitis implies a problem with local mucociliary defense, a defect in systemic immunity, or a fixed anatomic sinus obstruction. Often, the predisposing factors work in tandem, as in a child with a septal deformity and a viral illness.¹²³ In chronic sinusitis, the mucosa is thickened, and marked edema, vessel dilation, and infiltration of inflammatory cells are present.²⁰⁵ Goblet cells are decreased in density, and seromucous glands are increased in density compared with their presence in normal sinuses.

Children with respiratory allergies are prone to sinusitis,^{60,112,162,161,163} and allergy is the second most prevalent predisposing factor in childhood sinusitis, acting through mucosal congestion and perhaps depressing local and systemic immune responses.^{114,169} The treatment of respiratory allergies may contribute to sinusitis because ciliary damage occurring after the administration of nasal decongestants has been shown in organ culture and animal studies.^{44,45,124} Richards and colleagues¹⁶⁹ reported a diagnosis of atopy in 62% of a selected cohort of pediatric patients who had documented recurrent sinusitis and were referred to allergy clinics in Los Angeles.

Defects of ciliary function, such as those occurring in cystic fibrosis, immotile cilia syndrome, and Kartagener syndrome, predispose a child to chronic sinusitis.^{54,89,100,163,174,192} Refractory sinusitis also occurs commonly in children with primary and acquired immunodeficiency

diseases.^{33,123,135,175,186,208,219} Immunocompromised children undergoing treatment for malignancies and organ transplantations constitute a growing population with a potential for developing sinusitis that is difficult to manage. Finally, anatomic obstruction caused by septal and turbinate deformities, craniofacial anomalies, foreign bodies, adenoidal hypertrophy, or nasal masses or polyps predisposes children to sinusitis. Nasal polyps in young children usually are not caused by allergies and should be an indication for evaluation for cystic fibrosis.¹²³ In addition, biofilms may play an important role in chronic sinusitis and are thought to produce persistent disease despite maximal medical and surgical therapy.^{137,185}

Immunologic mechanisms are important in the pathogenesis of sinus infections, as indicated by the high prevalence of chronic sinus infections in children with immunodeficiencies.^{33,36,123,135,175,186,190,208} Sinonasal mucus contains IgA, IgG, IgM, and lysozymes.^{28,173} Secretory IgA, which is produced locally, is the predominant immunoglobulin in nasal mucus.⁷⁸ IgG antibodies in nasal mucus result from passive leakage from plasma cells in the epithelium and submucosa and from the serum.¹⁹ Generally, with the patient's increasing age and as a result of previous exposures, these immunoglobulins develop species-specific and type-specific antibodies that block epithelial colonization by specific microorganisms.

Shapiro and associates¹⁸⁶ studied 61 children with refractory sinusitis and found that 34 had abnormal immunologic studies. Abnormal findings included poor response to pneumococcal type 7 antigen after immunization, IgG3 subclass deficiency, low serum IgA or IgG values, and elevated serum IgE values.

ETIOLOGY

Table 14.1 lists etiologic agents of sinusitis by age of patient and type of illness. In all age groups and in acute, subacute, and chronic disease, *Haemophilus influenzae* and *Streptococcus pneumoniae* are the principal pathogens in most cases. Also, a large number of different bacterial species have been recovered from the sinuses of affected patients. In young children, more than 90% of all cases of sinusitis are caused by five organisms: *H. influenzae*, *S. pneumoniae*, *Moraxella catarrhalis*, *Staphylococcus aureus*, and *Streptococcus pyogenes*. Concern has been raised as to whether *S. aureus* is a cause of sinusitis in children.²²³ This concern is based on the fact that *S. aureus* is common in the noses of all children, and therefore there is likely contamination at the time of maxillary sinus puncture or endoscopic surgery. Similar concern should also be raised regarding α -hemolytic streptococci, coagulase-negative *Staphylococcus*, and various anaerobes because they also are part of the nasal flora. In adolescents, the same organisms, plus largely penicillin-sensitive anaerobes, account for most cases. As noted in Table 14.1, a variety of gram-negative enteric and other bacilli have been recovered from patients with sinusitis, in most instances from patients who have had various forms of antibiotic therapy before culture. Organisms previously considered to be nonpathogens, such as *Staphylococcus epidermidis*, have been implicated etiologically.

Although clinically recognized sinusitis has occurred rarely in patients with *Mycoplasma pneumoniae* infection, Griffin and Klein⁶⁹ noted radiographic evidence of sinusitis in approximately two-thirds of a group of U.S. Navy recruits with *M. pneumoniae* pneumonia. In adults with chronic suppurative maxillary sinusitis, mycoplasmas have been sought but not recovered.^{16,67,199} Bhattacharyya and colleagues¹⁶ noted L-forms in 21% of all sinuses in patients with chronic disease.

In a study of 25 adults with chronic rhinosinusitis, *Chlamydomphila pneumoniae* was recovered from nasopharyngeal samples in 2 patients but not from any of 10 healthy controls.⁵³ In addition, the patients were more likely than control subjects (20%) to have serum IgG antibody titers to *C. pneumoniae* of 1:64 or greater (72%). IgA antibody titers to *C. pneumoniae* of 1:32 or greater also were more prevalent in the patients (48%) than in the controls (10%). In a study involving 20 children with chronic sinusitis, Cultrara and colleagues³⁸ cultured material from 13 bilateral endoscopic ethmoidectomies with maxillary antrostomies, 10 adenoidectomies, and 3 bilateral maxillary sinus lavages. They isolated *C. pneumoniae* from a nasopharyngeal swab and adenoid tissue from a 6-year-old child.

Data from references 9, 16, 21–23, 27, 30, 33, 38, 51, 53, 57, 58, 66, 67, 90, 96, 97, 101, 105, 114, 115, 121, 132, 145, 163, 165, 211, 214, 215, 225, 229, 230, 237.

Fungal diseases of the sinuses have been well described in adults.²³³ *Aspergillus* spp. are the most common fungal causes of sinusitis. Many cases of chronic sinusitis from which a microorganism is not recovered have been thought to be caused by *Aspergillus* spp. infections.⁹⁹ The presence of eosinophils, Charcot-Leyden crystals, and hyphae found retrospectively, and not noted on the original examination, in mucus recovered from sinuses suggests that some cases of chronic sinusitis may represent *Aspergillus* hypersensitivity. This allergic aspergillosis in the sinuses is similar to allergic bronchopulmonary aspergillosis. In a series of six patients who were 8 to 16 years of age and had allergic aspergillosis sinusitis, all presented with nasal polyposis and facial deformity, indicating advanced disease.¹²⁵ Acute fulminant fungal sinusitis, such as mucormycosis, which is caused by Zygomycetes (formerly Phycomycetes), is seen in immunosuppressed individuals and is associated with high morbidity and mortality rates.^{42,95,196} *Drechslera* spp., *Bipolaris*

spp., *Scopulariopsis* spp., *Candida* spp., and *Curvularia lunata* can cause sinusitis in children.^{15,27,58,66,115,194}

Although sinusitis has been reported as a complication of Epstein-Barr virus infection, the sinus infections seem to be a complication of corticosteroid treatment and not specifically the viral infection.⁶³ *Nocardia* spp. have been reported as a cause of acute sinusitis in an adult transplant recipient¹⁷⁰ and of chronic sinusitis in immunocompetent and immunocompromised individuals.²¹⁰

EPIDEMIOLOGY

Although sinus involvement occurs commonly with viral infection of the respiratory tract, sinusitis seldom is identified as a specific illness in previously healthy children. In a survey of a total of 2613 office visits, Breese and colleagues²⁰ noted only six children (0.23%) in whom the

initial diagnosis was sinusitis. The true incidence of sinusitis in childhood is unknown. In 1989, Wald and colleagues²²⁵ estimated that 0.5% to 5% of upper respiratory tract infections are complicated by acute sinusitis. More recent estimates by the same authors have been 10%.²²⁸ The most recent estimates of greater incidence could be related to a heightened awareness and concern for lost work days by working parents, a possible correlation between pulmonary problems in an increasing number of children with chronic lung disease, better imaging techniques, increased interest in endoscopic sinus surgery,²⁰⁴ more disease because of more exposure as a result of more children being in daycare,¹²³ and an increased recognition or perhaps incidence of allergy-related illness.^{168,169} Seasonal prevalence has not been studied, but a reasonable assumption is that disease would increase during the cold weather months because it is the time of greatest respiratory viral activity. Cases in older children also can be expected to occur more frequently in association with swimming.

Shapiro and colleagues¹⁸⁵ used data from the National Ambulatory Medical Case Survey and National Hospital Ambulatory Medical Case Survey between 1998 and 2007 and found that the annual visit rate for acute sinusitis for children younger than 18 years of age ranged between 11 and 14 visits per 1000.

Although it is not well documented, sinusitis seems to be more of a problem in geographic areas where marked temperature changes occur. In children, sinusitis seems to occur more commonly in boys than in girls.^{81,131} Ueda and Yoto²⁰⁷ found abnormal findings in the maxillary sinuses in 135 (6.7%) of 2013 children who presented to an outpatient department with upper respiratory symptoms; of this group, 65% were boys and 35% were girls. Manning and associates¹²⁴ found similar distribution in a group of 60 children diagnosed by CT or magnetic resonance imaging (MRI). Host factors are important in sinusitis because the illness occurs more commonly in allergic children; in children with chronic ear infections; and in patients with cystic fibrosis, primary humoral immunodeficiencies, and Kartagener syndrome.^{25,89,139,174} Although an association between sinus disease and asthma exists, controversy continues regarding whether sinusitis and other upper airway stimuli can induce asthma.^{59,169,180,243} A review of hospital admissions of patients with status asthmaticus at the Children's Hospital of Los Angeles showed a marked increase in admissions, and sinusitis was diagnosed in 23%.¹⁶⁸

Sinusitis is noncontagious from person to person, but point-source outbreaks are possible from swimming in heavily contaminated water. A cluster of seven cases of invasive nosocomial fungal sinusitis in severely neutropenic patients has been described. It was caused by the release of airborne fungal spores from soil reservoirs that were distributed during hospital construction during a 2-year period.¹¹⁷

CLINICAL PRESENTATION

The clinical symptoms of sinusitis vary by age. Older children and adolescents have localized complaints similar to those of adults, whereas in young children the findings are related less clearly to the sinuses.²¹⁷ The overall frequencies of symptoms, signs, and laboratory findings for acute, subacute, and chronic disease are presented in Table 14.2.

In young children, disease involves only the ethmoidal and maxillary sinuses. In these children, illness frequently has its onset after they have had an upper respiratory tract viral infection. A period of general improvement may occur, however, between the acute respiratory illness and the onset of symptoms related to sinus infection. The most prominent symptom in all children, and particularly in children younger than 10 years of age, is persistent rhinorrhea. The discharge frequently is purulent, but it occasionally can be serous or watery. Associated with rhinorrhea is cough, which becomes more prominent with increasing duration of disease. The cough particularly is troublesome at night because it is caused by the stimulation of the sinus drainage as it traverses the pharyngeal wall. The posterior drainage also occasionally causes vomiting. Fever is a variable occurrence in sinusitis and generally is related inversely to age and duration of illness. Malodorous breath often is reported by parents. The first evidence of illness in some children is fever and periorbital swelling. In most instances, periorbital cellulitis is a manifestation of ethmoidal sinusitis.

TABLE 14.2 Clinical Findings in Acute, Subacute, and Chronic Sinusitis in Children

	OCCURRENCE (%)	
	Acute and Subacute	Chronic
Symptoms		
Fever	50	20
Rhinorrhea	80	80
Cough (persistent and evening)	50	90
Pain/headache	30	30
Sore throat	20	20
Periorbital swelling	30	0
Vomiting	20	10
Allergic history	20	40
Malodorous breath	20	20
Signs		
Rhinorrhea	80	80
Temperature $\geq 38.3^{\circ}\text{C}$ ($\geq 101^{\circ}\text{F}$)	20	0
Sinus tenderness	20	10
Otitis media	40	60
Posterior pharyngeal pus	0	10
Transillumination positive	30	10
Periorbital swelling	30	0
Malodorous breath	20	20
Laboratory Findings		
Abnormal radiographs	100	100
Maxillary	90	90
Ethmoidal	40	40
Frontal and sphenoidal	10	10
Unilateral	70	10
Bilateral	30	90
Erythrocyte sedimentation rate elevation	50	10
White blood cell count elevation with an increased percentage of band form neutrophils	40	10

Data from references 3, 11, 81, 85, 94, 100, 103, 131, 139, 169, 174, 198, 220, 231.

Although facial pain and headache are frequent complaints of sinus disease in adults, they have been noted in only approximately one-third of the cases in children and are unusual occurrences in young children. The main symptom in older children and adolescents is rhinorrhea. In older patients with more chronic disease, the nasal symptoms may be minimal or absent. Troublesome postnasal drip is a frequent complaint.

Acute isolated sphenoidal sinusitis in children is rare but often misdiagnosed because the symptoms are vague and there are no specific physical findings.^{26,127} Findings include fever, headache, postnasal drip, and neurologic symptoms. Swimming and diving are possible predisposing factors.

Physical signs in sinusitis also differ by age. Nasal discharge is the most frequent finding in all age groups. Young children are more likely to have a serous or watery discharge, however, than are adolescents. Elevation of temperature occurs more commonly in acute disease and in association with orbital cellulitis. Sinus tenderness, a common finding in older patients, is noted only rarely in children. Particularly significant is tenderness with percussion of the upper molars. Examination of the throat frequently reveals free exudate. Occasionally the breath is malodorous.

The ears are abnormal in almost half of all patients with sinusitis. In acute disease in young children, it can be acute otitis media, but usually the findings are more suggestive of serous disease. Acute sinusitis frequently is unilateral, whereas chronic disease more often is bilateral.

Children with chronic sinusitis frequently have only minimal complaints. The parent notes that the child does not feel well and frequently reports that the child has had a persistent respiratory tract infection for months. In a series of children with chronic (>3 months) upper respiratory tract complaints who were referred to allergy clinics, 60% had sinusitis.¹³⁹ In this study, the combination of moderate to severe rhinorrhea and cough with minimal sneezing was reported to have a specificity of 95% and a sensitivity of 38% in predicting the presence of chronic sinusitis. In the referred children in this study, sinusitis was found in 63% of atopic children and in 75% of nonatopic children.

Laboratory studies other than cultures and radiography are not useful in the evaluation of a child with sinusitis. Herz and Gfeller⁸⁵ noted that in their study erythrocyte sedimentation rates were elevated in only approximately half of the patients, and leukocytosis occurred in only one-third. Generally, younger children with orbital cellulitis and ethmoidal sinusitis are more likely to have elevated sedimentation rates and white blood cell counts. The American Academy of Pediatrics (AAP) Subcommittee of Sinusitis and Committee on Quality Improvement has recommended that the diagnosis of acute bacterial sinusitis be based on clinical criteria in children who present with upper respiratory symptoms that are either persistent (nasal or postnasal discharge of any quality with or without daytime cough for >10 to 14 days) or severe (temperature >39°C [102.2°F] and purulent nasal discharge present concurrently for at least 3 or 4 consecutive days in a child who appears ill).⁵

COMPLICATIONS

Serious complications, including meningitis, osteomyelitis, cavernous sinus thrombosis, and epidural, subdural, brain, and orbital abscesses, occur in untreated sinusitis.* Ethmoidal sinusitis tends to present with orbital complications, while frontal sinusitis tends to produce intracranial complications. Classically, orbital complications of sinusitis follow a progression described by Chandler, evolving in the order of periorbital/preseptal cellulitis, orbital cellulitis, subperiosteal abscess, orbital abscess, and cavernous sinus thrombosis.³² Clinically, these complications can present in any order or skip stepwise progression. Signs and symptoms of neurologic involvement in sinusitis frequently call for aggressive surgical management of the sinusitis and the intracranial and paracranial lesions. Osteomyelitis of the frontal bone may be a complication of frontal sinusitis and may manifest as a Pott puffy tumor if a subperiosteal abscess also is present.

DIFFERENTIAL DIAGNOSIS

Differential considerations in sinusitis are few and are more concerned with whether sinus involvement in a particular child is the primary event or a secondary problem related to a more general host defect. Children with recurrent and chronic sinusitis should be evaluated for respiratory allergy, cystic fibrosis, immunologic deficiency, and Kartagener and other immotile cilia syndromes.

Foreign bodies in the nose can be mistaken for sinusitis, as can cysts in the maxillary antra. Nasal structural defects (congenital and acquired), such as palatal clefts, unilateral choanal atresia, nasal polyps, and septal deviation, can be confused with sinusitis, but more commonly these problems are predisposing factors in sinus infections.

Dental infections frequently are mistaken for maxillary sinus disease. Dental infections can lead by direct extension to sinus involvement. Primary infections in the region of the eye also occur without sinus disease. In young children, a chronic infection of the adenoids can be confused clinically with sinusitis. Infections with *Bordetella pertussis* can be confused with subacute sinusitis.

SPECIFIC DIAGNOSIS

Although persistent nasal symptoms and the presence of other clinical findings as listed in Table 14.2 indicate a diagnosis of sinusitis, the only

certain way to make the diagnosis is by obtaining radiographs and cultures reflecting sinus content. Although it has been suggested that maxillary sinus radiographs frequently are abnormal for normal children,^{126,191} other data indicate that normal children older than 1 year of age seldom have abnormal radiographs.¹⁰⁴ During infancy, the maxillary sinuses are so small that minimal mucosal edema may “opacify” a sinus on a radiograph. Radiographs in acute upper respiratory viral infections as a rule are abnormal; these radiographs are not false-positive ones but are the result of viral infections. From a therapeutic point of view, sinus radiographs usually should not be obtained unless nasal symptoms in an upper respiratory tract illness have not shown signs of improvement after 5 to 7 days.⁶

Plain film radiographic examination has been supplanted mainly by CT and MRI for the diagnosis of sinusitis. Many endoscopic sinus surgeons consider CT to be a mandatory part of the preoperative evaluation. MRI is useful in cases that may be complicated by orbital or intracranial extension. The high prevalence of incidental sinus opacification in asymptomatic infants and children noted radiographically has been confirmed by CT studies.^{44,64,87} Since the advent of MRI, researchers have realized that many incidental sinus abnormalities also occur in adults. These findings in children and adults may be from subclinical or resolving respiratory infections or may be due to unrecognized allergies.⁴⁴

CT has been recognized widely as the standard for the diagnosis of paranasal sinus disease.¹⁴ In particular, coronal thin-section images offer excellent delineation of lesions in the osteomeatal complex.²⁴⁴ Obtaining axial images is useful for evaluating periorbital and intraorbital complications.⁵⁶ In some institutions, a so-called screening CT of the sinuses is performed with a limited number of slices.⁷² It can be offered at a cost and radiation exposure that are similar to those associated with plain film studies but with much greater accuracy. Some young children and infants require sedation for CT, which limits its suitability.

The AAP Subcommittee of Sinusitis and Committee on Quality Improvement has recommended that imaging studies are not necessary to confirm a diagnosis of clinical sinusitis in children aged 1 to 18 years.^{5,224} The need for radiographic evidence as a confirmatory test in children older than 6 years with severe symptoms is controversial. The American College of Radiology considers that the diagnosis of acute uncomplicated sinusitis should be made only on clinical grounds.¹²⁹

Which radiographic technique (plain radiography, CT, or MRI) is selected for evaluation of a child with presumed sinusitis should be determined by availability of techniques and the expertise of the radiologist and by clinical symptoms. Radiography is indicated for children with continuing symptoms of sinusitis after extensive medical therapy or for children with possible complications of sinusitis. CT is optimal.^{6,224} A limited CT scan with axial cuts may be obtained. It allows for excellent visualization of sinus anatomy and pathology while limiting the radiation exposure to the child. A limited sinus CT scan has radiation similar to that of a sinus plain film series. In the absence of low-cost screening CT, plain radiography should be the initial imaging study in most children who have symptoms of sinus disease.⁴³ Children who have periorbital swelling or proptosis should undergo immediate contrast-enhanced CT studies in axial and coronal planes. If symptoms or CT findings suggest intracranial extension, MRI should be performed.^{6,43}

Although ultrasonography would seem to offer an alternative to sinus radiography, some question remains about its dependability unless one normal air-filled maxillary sinus or one opacified maxillary sinus is present for comparison.^{215,222} The hallmark of specific diagnosis in sinusitis is similar to that of other infectious diseases—the culture of infected material.

The definitive method for culture requires puncture of the sinus cavity. As noted in the section on etiology, false-positive findings may occur because of contamination by the nasal flora. Nevertheless, sinus puncture and drainage are imperative in immunocompromised patients who may have fungal or other life-threatening infections. Sinus puncture for culture is not necessary for children who have uncomplicated sinus infections. However, evidence of etiology can be obtained by bacterial culture from the nose at the level of the maxillary ostium in the middle meatus. Although many experts do not believe in the usefulness of this procedure, there is considerable evidence to support the culture findings

*References 1, 17, 40, 62, 63, 76, 86, 102, 108, 128, 134, 143, 144, 147, 150, 160, 176, 179, 187, 197, 206, 234, 236.

and etiology. Although the normal flora of the nasopharynx often contains the most common causes of sinusitis (i.e., *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *S. pyogenes*), the anterior nose does not.* Therefore we believe that properly performed nasal cultures will reveal the causative organism in many instances. This is particularly useful in the recovery of *S. pneumoniae*, which may be resistant to usual antimicrobial treatment.

Nasal culture should be taken from the region of the maxillary ostium in the middle meatus. Culture specimens should be obtained from this area and not from the nasopharynx. Best results are obtained when a vasoconstrictor, such as 0.25% phenylephrine hydrochloride, is administered first and the culture specimen is obtained with a cotton-tipped wire swab under direct vision. With this technique, material frequently can be obtained as it comes from the sinus ostium. Bilateral cultures always should be obtained. In serious cases, such as in children with neurologic complications or in treatment failures, performing antral puncture for culture can be lifesaving. Anaerobic and aerobic cultures should be performed on any material recovered by antral puncture.

TREATMENT

Acute and Subacute Sinusitis

The successful treatment of acute and subacute sinusitis in children depends primarily on the administration of an appropriate antibiotic in adequate dosage for a sufficient period.^{5,34,41,151,221,224,227} In most instances, therapy should be instituted before obtaining the results of cultures. Antibiotic selection in this situation is not a great problem in children because the etiologic agent is *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, *S. aureus*, or *S. pyogenes* in more than 90% of acute cases. Respiratory anaerobes are rarely the cause of acute bacterial sinusitis in children.²²⁴

Initial selection of an antibiotic should be based on the severity of the clinical illness and must take into consideration the antibiotic resistance patterns of the common causative organisms and the cost and ease of administration of the treatment regimen. Today, between 10% and 42% of nontypeable *H. influenzae* and close to 100% of *M. catarrhalis* strains produce β -lactamases and are resistant to amoxicillin.^{46,47,224} In addition, 15% to 38% of *S. pneumoniae* strains have either intermediate (7–19%) or complete (5–19%) penicillin resistance.^{12,29,48,224}

In 2012, the Infectious Diseases Society of America (IDSA) published its clinical practice guidelines for acute bacterial rhinosinusitis,³⁴ and in 2015, the AAP updated its guidelines for acute bacterial sinusitis in children.²²⁴ These two guidelines often present challenges in pediatric practice because of the overemphasis of their “guideline definitions for evidence based statements.” The current AAP committee recommendations are very similar to the recommendations in 2001.^{5,224} The AAP committee states that “amoxicillin remains the antimicrobial agent of choice for first-line treatment of uncomplicated acute bacterial sinusitis in situations in which antimicrobial resistance is not suspected.” The dose recommended is 45 mg/kg/day in two divided doses. In communities with a high prevalence of nonsusceptible *S. pneumoniae*, an amoxicillin dose of 80 to 90 mg/kg per day in two divided doses is suggested.

The committee qualifies the preceding recommendations for children with moderate to severe illness, children younger than 2 years of age, children attending daycare, and children who had recently been treated with an antimicrobial agent. For this group, high-dose amoxicillin-clavulanate (80 to 90 mg/kg per day of the amoxicillin component and 6.4 mg/kg per day of clavulanate in two divided doses with a maximum of 2 g per dose).²²⁴

For children who are vomiting, who are unable to tolerate oral medication, or where adherence to the oral regime could be a problem, a single 50 mg/kg dose of ceftriaxone (either IV or IM) is suggested.²²⁴

In contrast with the AAP committee guidelines, the IDSA suggests that amoxicillin-clavulanate rather than amoxicillin alone be the empiric antimicrobial therapy for acute bacterial sinusitis in the children.³⁴

In contrast to the AAP committees’ recommendations, we consider that an approach as noted by the IDSA, to use amoxicillin-clavulanate 90 mg/kg per day in two divided doses, would be more suitable.^{5,34,224} The duration of treatment in the outpatient setting has not been studied adequately. Wald²²⁰ suggests that therapy should be continued for 7 days after the child becomes symptom free.

The AAP committee carefully looked at treatment for children who have a history of “penicillin allergy.”²²⁴ It is noted that the risk of a serious reaction to a second- or third-generation cephalosporin in a child with reported penicillin allergy is almost nil. Therefore it is suggested that these patients can be safely treated with cefdinir, cefuroxime, or cefpodoxime. It is also suggested that a child who had a past type I immediate or accelerated (anaphylactoid) reaction to amoxicillin can also safely be treated with the same cephalosporins. However, they indicated that the clinician may want to seek consultation with an allergist in the latter situation.

A seriously ill child should be hospitalized, and therapy for β -lactamase-producing staphylococci and highly resistant pneumococci should be implemented in addition to coverage for amoxicillin-resistant *H. influenzae* and *M. catarrhalis*. This coverage is achieved with vancomycin 40 mg/kg per 24 hours every 6 hours and cefotaxime 100 to 200 mg/kg per 24 hours every 6 hours or ceftriaxone 100 mg/kg per 24 hours every 12 hours. Therapy should be adjusted on the basis of clinical response and culture results. The dosage and duration of antimicrobial therapy in sinusitis are crucial considerations. Penicillins penetrate the sinuses poorly.^{10,55,73,95,118} The duration of therapy should be a minimum of 10 days.

The relief of obstruction at the sinus ostia and the establishment of drainage are time-honored principles of therapy. To achieve these goals, locally applied and systemically active vasoconstrictive drugs are used. To date, no evidence supports their therapeutic effectiveness, however.^{182,183} The beneficial effects of oral, systemically active, vasoconstrictive drugs are hampered by the fact that their drying effect may be deleterious to the mucus blanket. Topical vasoconstrictor drugs (e.g., phenylephrine hydrochloride and oxymetazoline) are plagued by rebound vasodilation. We consider that these drugs should be used rarely in acute disease; their main use is to relieve pain caused by obstruction, and they should be used only for 2 to 3 days.

Systemic and intranasal corticosteroids have been used in acute sinusitis as monotherapy and in conjunction with antimicrobial agents.^{83,213,242} Data on corticosteroid use mainly involve adult patients, and the onset of action is generally on the order of weeks. It is our opinion that corticosteroid use in acute sinusitis in children should be discouraged.

Chronic and Recurrent Sinusitis

Allergic disorders are common in chronic and recurrent sinusitis.^{123,151,218} Children should be evaluated for allergy, and, when identified, specific treatment should be employed. Specific allergens and irritants should be avoided (e.g., through air filtering, removal of pets, avoidance of tobacco smoke), and pharmacologic management should be implemented.

Nasal saline irrigations (twice daily in each nostril) are useful because they liquefy secretions, dilute antigens and environmental toxins, and enhance mucociliary transport, which improves sinus drainage and ventilation.²³² Antihistamines may be useful if allergic rhinitis is a contributing factor to the chronic sinus infection. Antiinflammatory agents also may be useful. In selected cases, use of either topically applied corticosteroids or cromolyn sodium may be beneficial. Corticosteroids should be used carefully because their use occasionally can lead to superinfection in the sinuses with *Pseudomonas* spp., other highly resistant gram-negative bacilli, or fungi. For effective corticosteroid use, Wald²¹⁸ suggests using a topical decongestant first so that the corticosteroid preparation can reach the affected areas better.

In chronic or recurrent disease, antimicrobial treatment should be based on culture and sensitivity data. Specific antimicrobial agents are the same as the agents used in acute and subacute disease, but treatment should be prolonged for 3 weeks or more and for 7 days after the resolution of symptoms. In 2004, Kuhn and Swain¹⁰⁷ defined allergic fungal sinusitis in adults by five major criteria: (1) type I IgE-mediated

*References 18, 52, 61, 68, 77, 79, 80, 82, 88, 89, 92, 93, 97, 121, 131, 142, 188, 211, 214, 215, 225, 229, 230, 235, 241.

hypersensitivity, (2) nasal polyps, (3) characteristic CT imaging, (4) allergic mucin within the sinuses, and (5) positive fungal smear. McClay and colleagues¹³⁰ and Campbell and associates²⁷ have further characterized allergic fungal sinusitis in the pediatric population. It typically presents in atopic children with recurrent sinusitis and nasal polyps. Children, when compared with adults with allergic fungal sinusitis, typically present with more facial abnormalities, including proptosis, and they present more frequently with unilateral disease or asymmetric disease. Surgical intervention is a mainstay of treatment for acute fungal sinusitis, with nearly half the patients requiring multiple procedures.²⁷ Allergic fungal sinusitis is typically refractory to medical management until the fungal allergic mucin is first debrided and the sinus cavities are marsupialized for postoperative irrigation.

Aspergillus and *Bipolaris* spp. and other fungal infections require prolonged therapy with an antifungal agent to which the specific agent is susceptible. Itraconazole, ketoconazole, fluconazole, and amphotericin B all have been effective in selected cases. Allergic fungal sinusitis can be treated with endoscopic sinus debridement of all fungal and polypoid disease, followed by topical and systemic corticosteroids and close follow-up, including frequent endoscopic cleaning.^{37,108,109,159} Allergic aspergillosis of the sinuses can be managed with topical corticosteroids without specific antifungal therapy (see Chapter 23).

In the past, surgical therapy for sinusitis in children was of questionable benefit. Surgical therapy included diagnostic and therapeutic irrigation; permanent drainage procedures in children with complications of sinusitis and in children who had immune defects; and such procedures as adenoidectomy,^{111,209} septoplasty, and turbinate reduction to relieve anatomic obstructions to improve nasal and sinus ventilation. In one uncontrolled study of children with otitis media with effusion and sinusitis, the sinusitis was improved 6 months after adenoidectomy in 56% of children, whereas only 24% of similar children who did not undergo surgery had similar improvement.²⁰²

Historically, creating nasoastral windows was the most common major surgical procedure for treating chronic sinusitis in children.^{70,136} Long-term success with this procedure was poor, however, because of the high rate of closure of the windows. A new interest in sinus surgery has resulted from the introduction of endoscopic techniques. Several studies have found endoscopic surgery to be safe and effective.^{71,110,120,154,171} Pediatric endoscopic sinus surgery now is recognized as a viable option for children with chronic recurrent sinusitis refractory to medical therapy.^{31,113,164} A meta-analysis of 832 children who underwent endoscopic sinus surgery from 1986 to 1996 revealed an overall 88.4% positive outcome after surgery,⁸⁴ with a complication rate of 1.4%.¹²²

The goal of functional endoscopic sinus surgery is to remove obstruction at the osteomeatal complex where the mucociliary flow from the frontal, maxillary, and ethmoidal sinuses converges.^{110,171} This process results in improved drainage and restoration of normal physiologic function of the frontal, maxillary, and ethmoidal sinuses. Surgery generally involves a maxillary antrostomy, or surgical enlargement of the natural ostium of the maxillary sinus, anterior ethmoidectomy, and depending on the extent of disease, posterior ethmoidectomy as well. The sphenoid and frontal sinuses are often not yet developed in young children; surgical treatment of these sinuses should only occur if the sinus is present and if there is evidence of disease. Follow-up debridement performed 2 to 3 weeks after the initial surgery sometimes is necessary to remove crusts, blood clots, any stenting material, granulation tissue, and adhesions.²³¹

In a study of 210 children with a history of chronic sinusitis for 3 months or longer, functional endoscopic sinus surgery resulted in successful outcomes in 165 (79%).¹¹⁰ The follow-up period was 3 to 36 months (mean, 18 months), and all of the infections in these children had failed to respond to prior extensive medical management. In this series, no major complications occurred.

Functional endoscopic sinus surgery should be considered for children with chronic or recurrent sinusitis that has failed extensive, prolonged, and adequate medical management.¹¹³ There have been recent advancements in image guidance for pediatric sinus surgery. Image-guided surgery was first introduced for neurosurgical procedures and was quickly adapted by otolaryngologists in the 1990s for revision sinus surgery.

The indications for image-guided surgery were expanded by the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS) to include patients with any distorted sinus anatomy, those with extensive sinonasal polyposis, pathologic processes in the frontal, posterior ethmoidal, or sphenoidal sinuses, and patients undergoing skull base surgery.^{4,98,178} Image-guided surgery has not been as well studied in the pediatric population as it has in the adult population¹¹⁹; however, the largest series to date, by Postec and coworkers¹⁵⁵ suggests a similar utility in the pediatric population to that of the adult population. A recent literature review by Parikh and associates¹⁴⁶ showed that image-guided surgery can be safely utilized in children with chronic sinusitis, in those undergoing revision surgeries, and in any patient in whom the anatomy may be distorted, without increasing the rate of intraoperative complications.

Balloon catheter sinuplasty is another recent advancement in the treatment of sinus disease. This technology was first introduced in 2006 and provides a less invasive technique for enlargement of the sinus ostium. It involves the placement of a guide wire under fluoroscopic or fiberoptic light confirmation into a sinus cavity and the inflation of an oblong balloon to dilate the natural ostium by approximately 5 mm.²⁰⁰ The main advantage of this technology is that, unlike traditional functional endoscopic sinus surgery, balloon catheter sinuplasty provides a mucosal sparing technique without inadvertent removal of tissue. To date, there are no published prospective trials comparing functional endoscopic sinus surgery to balloon catheter sinuplasty in the pediatric population. The major limitation of balloon catheter sinuplasty is the inability to address other anatomic abnormalities such as a malpositioned uncinate or ethmoidal disease. A limited number of studies demonstrate that balloon catheter sinuplasty is safe and efficacious in reducing sinus symptoms up to 1 year post procedure.^{165–167} However, Ramadan and Terrell¹⁶⁷ also showed that the same reduction in symptoms was also accomplished with standard maxillary sinus irrigation plus adenoidectomy performed in children with chronic or recurrent sinusitis.

Many pediatric otolaryngologists have resumed performing adenoidectomy as a surgical intervention before proceeding with functional endoscopic sinus surgery.¹⁹⁵ It is thought that adenoidectomy removes a reservoir of bacteria that contributes to chronic or recurrent sinus infections.^{189,193} Recently there has been a renewed interest in evaluating both endoscopic sinus surgery and adenoidectomy and clarifying indications for each. In 2004, Ramadan¹⁶⁴ performed a prospective nonrandomized study evaluating endoscopic sinus surgery and adenoidectomy. In this study, 202 children were divided into three groups, with group 1 receiving endoscopic sinus surgery with an adenoidectomy, group 2 receiving endoscopic sinus surgery alone, and group 3 receiving only an adenoidectomy. After 1-year follow-up, it was found that group 1 had 87% improvement in symptoms, compared with 75% and 52% in groups 2 and 3, respectively. After multivariate analysis of risk factors such as asthma, smoke exposure, and age, Ramadan concluded that adenoidectomy alone is recommended for children younger than 6 years without asthma. Children with asthma at any age or children older than 6 years with significant disease on the CT scans benefit from endoscopic sinus surgery at the time of the adenoidectomy. Other studies examining the efficacy of adenoidectomy alone in alleviating symptoms of chronic or recurrent sinusitis have demonstrated a range from 50% to 70%.^{203,212} A meta-analysis of pediatric patients treated with endoscopic sinus surgery found symptomatic improvement in nearly 90% of patients.⁷⁵

In conjunction with endoscopic sinus surgery, specific antimicrobial therapy for organisms identified by culture is carried out. In addition, other contributing conditions, such as cystic fibrosis, asthma, or immunologic disorders, need to be addressed.

Orbital and intracranial abscesses and cavernous sinus thrombosis secondary to sinus infection require emergent surgery, which often is lifesaving, to evacuate the source of infection.^{172,176,234,236} Within the spectrum of orbital complications, management of subperiosteal abscess is more controversial. In a combined review of 134 patients with subperiosteal abscess of the orbit, medial abscesses (adjacent to the lamina papyracea) are most likely curable by antimicrobial therapy alone, but surgery may be indicated in cases of abscesses in

other locations, those with loss of visual acuity, and abscesses refractory to 48 to 72 hours of medical therapy.³⁵ Cellulitis, osteomyelitis, and meningitis also frequently require surgery if they do not respond to antimicrobial therapy.¹⁷² Surgery in these cases involves endoscopic drainage of the sinuses and abscesses. Endoscopic techniques may allow for intranasal drainage and avoidance of the development of facial scars.⁷ If an intracranial complication involves an intracranial empyema or abscess, concomitant craniotomy along with functional endoscopic sinus surgery may be required.⁶⁵ Surgical procedures also may be indicated for a child with acute or chronic disease resulting from an identified underlying problem, such as an immunologic deficiency.²³⁸

PROGNOSIS

The prognosis for identified and adequately treated sinusitis in otherwise normal children is excellent. Frequently children have subnormal health because sinusitis goes unrecognized; it may be treated only partially because of other clinical impressions, which contributes to the chronicity of the problem. Sinusitis is likely to be recurrent in children with a history of previous chronic disease and in children with repeated adverse exposure, such as swimming in contaminated or irritating water. Children with allergic respiratory disease also are likely to have frequent recurrences. Sinusitis in an immunocompromised child frequently is resistant to cure; long-term continuous therapy can be beneficial in such patients. Signs and symptoms of neurologic involvement in sinusitis frequently call for aggressive surgical management of the sinusitis and the intracranial and paracranial lesions, and timely management is highly impactful.

Paranasal sinusitis also has been noted occasionally to be associated with bronchial asthma.^{152,162} Its successful treatment has resulted in clearing of the asthma.^{91,180}

PREVENTION

Sinusitis is not preventable in most instances. In some individuals, change of lifestyle can do much to improve the situation, however. Sinusitis in some children is related to their swimming habits and can be controlled by elimination of swimming or perhaps by the use of nose plugs. Good allergic management, including intranasal corticosteroid or cromolyn therapy, prevents sinus disease in certain atopic children. Relief of nasal airway obstruction caused by allergic rhinitis, enlarged adenoids, or other anatomic problems also should help to prevent sinusitis. Early attention given to persistent nasal discharge also can be expected to lessen the damage associated with sinus infection.

In Sweden, the universal use of pneumococcal conjugate vaccine decreased the risk of hospitalization for sinusitis by 66%.¹¹⁶ At Texas Children's Hospital, the use of 13-valent pneumococcal vaccine resulted in a decrease in *S. pneumoniae* isolations from children with chronic sinusitis.¹⁴¹

Otitis Externa

Ellen M. Friedman • Maria Carrillo-Marquez

Otitis externa is an inflammation of the external ear canal commonly caused by infection. It constitutes one of the most common otolaryngologic encounters in the emergency department. This condition is addressed commonly as *swimmer's ear* or *tropical ear* because it often occurs after a history of repeated water exposure and occurs more commonly in warm and humid environments. This condition became

of significant interest during World War II because of its high incidence among the troops in the South Pacific. During World War II, otitis externa accounted for 50% to 70% of the caseload for otolaryngologists in the South Pacific.³¹

Today, otitis externa accounts for 7.5 million annual ototopical prescriptions in the United States and is a significant cause of ear pain

and conductive hearing loss.⁶³ This chapter discusses the basic anatomy of the external canal, different etiologies of otitis externa, and treatment and prevention that are needed by the pediatric practitioner managing this condition.

EPIDEMIOLOGY

According to the Centers for Disease Control (CDC), in 2007, the burden of acute otitis externa in the United States was 2.4 million health care visits (8.1 visits/1000 population), an estimated 1/123 persons affected during that year. Estimated annual rates of ambulatory care visits for acute otitis externa between 2003 and 2007 were highest among children 5 to 9 (18.6%) and 10 to 14 years of age (15.8%). Approximately 3% of emergency department visits for acute otitis externa in 2007 led to hospitalization. Incidence peaked during summer months, and the regional rate was highest in the South. Direct health care costs were approximately \$0.5 billion annually and nearly 600,000 hours annually of clinician's time.¹⁵ In a retrospective analysis of the Nationwide Emergency Department Sample from 2009 through 2011, more than 8.6 million visits were due to an otologic diagnosis, which represented 2.2% of all emergency department and 6.7% of all pediatric emergency department encounters. Otitis externa accounted for 11.8% of all the cases.⁴³

Otitis externa was the most common cause of outpatient visits for waterborne disease between 2005 and 2006.²⁴ Outbreaks of otitis externa have been identified in competitive swimmers in association with insufficiently chlorinated pools,⁵⁶ in divers,³ and in association with swimming in recreational fresh water lakes.⁸⁰

NORMAL ANATOMY

The external ear is composed of the auricle and external auditory canal. The auricle of the ear is a skin-covered cartilaginous structure on the temporal region of the head and is an extension of the external auditory canal. The external auditory canal is divided into two regions: a lateral cartilaginous portion and a medial bony portion that ends at the tympanic membrane.

The cartilaginous portion of the external auditory canal makes up approximately 40% of its 2.5 cm total length and typically is directed slightly upward and backward. This shape and the presence of cerumen help to prevent water and foreign objects from entering the canal.⁴¹ In the anterior portion of the cartilaginous canal are the fissures of Santorini, which provide a route for the spread of infection from the canal into the adjacent parotid and surrounding tissues. The bony canal makes up the remainder of the canal length and is directed slightly downward and anterior. The isthmus, which is the narrowest portion of the canal, corresponds to the bony-cartilaginous junction.

The sensory innervation of the external auditory canal is complex and includes contributions from cranial nerves V, VII, IX, and X. This robust sensory innervation is responsible for the exquisite pain associated with otitis externa.⁴¹ The skin of the entire external auditory canal consists of keratinizing stratified squamous epithelium. It is the only keratinizing epithelium that lacks eccrine sweat glands.

Differences exist in the canal skin of the cartilaginous canal and the skin covering the bony canal. The cartilaginous canal skin is thicker and contains rete pegs, dermis, dermal papillae, hair follicles, and sebaceous and cerumen glands, which are absent in the bony canal. The thinner skin of the bony canal lacks dermal papillae and rete pegs. The lack of subcutaneous tissue in the bony canal allows the tight attachment of the skin to the underlying periosteum, rendering the bony canal wall more vulnerable to trauma.

PROTECTIVE MECHANISMS OF THE EXTERNAL EAR

Three major defense mechanisms protect the external auditory canal and lateral surface of the tympanic membrane: the tragus and antitragus, the skin with its cerumen coat, and the isthmus of the canal. The tragus and antitragus provide a partial barrier to the entrance of the foreign bodies into the external auditory canal.

BOX 15.1 Predisposing Factors for Otitis Externa

- Hot and humid environment
- Water exposure
- Instrumentation of ear canal
- Previous radiation therapy
- Draining ear
- Contact dermatitis

The skin of the cartilaginous canal contains many hair cells and sebaceous and apocrine glands, such as cerumen glands. Together, these three adnexal structures are termed the *pilosebaceous unit* and provide a protective function in the external auditory canal. Migration of the skin of the external auditory canal also helps keep the canal free of debris. The pattern of migration is from the tympanic membrane laterally and radially away from the umbo.² Glandular secretions combine with sloughed squamous epithelium to form an acidic coat of cerumen, one of the primary barriers to infection of the canal. Cerumen is composed of lipids that are hydrophobic, and its major function is to waterproof the canal. The acidic nature of cerumen has been shown to inhibit bacterial and fungal growth.^{16,26,37} This acidic pH also helps maintain the cohesion and integrity of the stratum corneum.³²

Racial and gender differences that are noted in the characteristics of cerumen do not seem to have major clinical significance. Whites and blacks produce cerumen with higher levels of lipids in contrast to Asians, who produce cerumen with higher levels of proteins. Cerumen in males also has been shown to have a higher pH level than that in females.²⁶ The canal normally is a self-protecting and self-cleansing structure. The cerumen coat gradually works its way to the lateral part of the canal and sloughs externally. Instrumentation and excessive cleansing of the canal can alter this primary protective barrier and may lead to infection (Box 15.1).

NORMAL BACTERIAL FLORA

The normal bacterial flora of the external auditory canal is a combination of aerobic (80%) and anaerobic (20%) organisms.¹² Aerobic bacteria include *Staphylococcus epidermidis*, *Pseudomonas aeruginosa*, α -hemolytic streptococci, and diphtheroids.

The bacteriology of the cerumen and the external auditory canal is essentially the same. In a study by Stroman and colleagues⁷⁹ of 291 bacteria isolated from cerumen and 302 bacteria isolated from the canal, 99% and 96%, respectively, were gram-positive. Staphylococci accounted for 63% of bacteria. *Staphylococcus auricularis* is the isolate found most frequently (23% in cerumen and 21% in the canal), followed by *S. epidermidis* (14% from cerumen and 17% from the canal, respectively). After staphylococci, the coryneform bacteria (diphtheroids) are the organisms most frequently isolated. The third most frequently recovered bacteria belong to the streptococci and enterococci groups. *Alloicoccus otitidis* was isolated with the greatest frequency (>95%).⁷⁹

In addition, seven species of *Bacillus* were isolated. From the Micrococcaceae family, *Micrococcus luteus* was isolated most frequently. *Turicella otitidis* was the primary coryneform recovered—58% from cerumen and 65% from the canal. *Corynebacterium auris* was the second most frequently isolated coryneform, accounting for approximately 12% of bacteria. Twenty-one other species of coryneform bacteria (including 10 previously undefined species of *Corynebacterium* and 4 of *Microbacterium*) were isolated as well. Coryneform bacteria represented approximately 20% of the bacteria isolated. *Propionibacterium acnes* and a variety of *Peptococcus* spp. make up the anaerobic flora.⁷⁹

ACUTE OTITIS EXTERNA

Acute otitis externa is an infection of the external auditory canal that often is the end result of a combination of factors. Bacterial and fungal infections of the external auditory canal occur when the natural defenses break down, resulting in a significant reduction in the amount of cerumen, an injury to the skin of the canal, or a shift of the normal

canal flora. Humidity, heat, and maceration all produce itching, which often leads to manipulation and instrumentation of the canal, which in turn leads to additional trauma. Otitis externa may be caused by insults that result in the removal of the protective lipid film from the canal, allowing the entrance of organism to the apopilosebaceous unit. Rapid proliferation of bacteria occurs as a result of the warm, dark, and moist canal environment.

Inflammation and infection can cause canal edema or complete obstruction of the canal in severe cases, with purulent discharge. If the infectious process goes untreated, it leads to cellulitis of the auricle and surrounding area.

Symptoms of otitis externa, in addition to pruritus and drainage, include pain and tenderness on palpation or manipulation of the external ear. Pain arises as the soft tissues and skin of the canal distract the periosteal lining of the bony canal. Pain is severe and may interfere with daily activities and is the major reason for medical consultation.

History and Physical Examination

Otitis externa is a clinical diagnosis. The evaluation often reveals exposure to water, previous auricular instrumentation, or trauma. The physician should inquire about predisposing factors, such as diabetes, immunosuppression, history of eczema, or previous radiation therapy, all of which may predict a more complicated course.

Symptoms of acute otitis externa include otalgia (70%), itching (60%), fullness (22%), with or without hearing loss (32%) or ear canal pain on mastication.⁶⁴

On physical examination, the pinna may appear swollen or erythematous with eczematization (Fig. 15.1) or may be protruding. Primary care practitioners and emergency department personnel may erroneously consider the diagnosis of mastoiditis based on auricular protrusion. On manipulation of the auricle, the patient often experiences severe pain. Tragal tenderness is another key feature of this disease. A handheld otoscope often suffices to establish the diagnosis, but the microscope is recommended for full cleaning of the ear canal. The canal appears swollen, with various grades of patency, depending on the severity of the infection. Purulent discharge combined with keratin debris usually fills the canal. It is important to attempt to visualize the tympanic membrane if the canal is not completely obstructed. Absence of drainage from the middle ear confirms the diagnosis of otitis externa.

Pathogens in Acute Otitis Externa

Common bacterial pathogens that cause otitis externa include *P. aeruginosa*, *Staphylococcus aureus*, *Escherichia coli*, and *Proteus* spp. (Box 15.2). *Pseudomonas* spp. have been found to be the predominant organism in various studies.^{8,11,62,72} Historically, *Pseudomonas* spp. have accounted for 50% to 80% of bacteria isolated from cases of chronic otitis externa.^{7,52,54,62,72} In a study by Roland and Stroman,⁶² gram-negative bacteria accounted for 53% of recovered organisms; 45.3% were gram

positive. In this study, *P. aeruginosa* accounted for 37.7% of the total number of isolates, whereas *Pseudomonas otitidis* accounted for 2.3% of recovered organisms.

Staphylococci are the most common gram-positive organisms recovered in cases of otitis externa, accounting for 25% of the cases. *S. epidermidis* is the most common staphylococcal species recovered, followed by *S. aureus*. Coryneform bacteria are the second largest group of gram-positive bacteria isolated from cases of otitis externa.⁶² Reports of methicillin-resistant *S. aureus* as an increasing pathogen isolated from otorrhea resulting from otitis externa showed variable prevalence: 0.3%,⁶² 5.3%,⁵⁰ 6.3%,⁸² and up to 9.8% of cases.³⁶

Other organisms identified as pathogens include *Enterobacter*, *Klebsiella*, *Serratia*, and *Proteus* spp. and *E. coli*. Although *Microbacterium* spp. previously were considered normal flora, more recently they have been identified at a 10 times higher rate in infected ears in contrast to normal controls. *Microbacterium* also has been the single recovered isolate in treatment failures and reinfections.⁶²

Management of Acute Otitis Externa

No consensus exists about the most effective treatment for otitis externa; however, evidence-based guidelines have been published with strong recommendations issued for acute uncomplicated infection in patients older than 2 years of age including pain assessment and appropriate analgesic prescription and avoidance of systemic antibiotics for initial therapy unless there is extension outside the ear canal or the presence of specific host factors that would indicate a need for systemic therapy. In addition there is continued strong support for treatment to include meticulously cleaning the external auditory canal. It is also important to differentiate acute otitis externa from other pathologies with similar symptoms, identify factors that modify management (i.e., nonintact tympanic membrane, tympanostomy tube, diabetes, immunocompromised state, prior radiotherapy), implement strategies to improve the delivery of topical drops (aural toilet, wick placement, drop administration instructions, etc.), consider use of a nonototoxic preparation in patients with known or suspected tympanic membrane perforation or tympanostomy tubes, and reassess if the patient fails to respond to treatment within 48 to 72 hours to either confirm the diagnosis or to exclude other causes of illness.⁶⁴

Treatment usually includes thorough cleaning and suctioning of the purulent debris and application of topical agents. Topical treatment has been shown effective and is the mainstay of treatment. A wick may be placed in the canal to provide adequate delivery of the topical solution when significant swelling of the external auditory canal occurs. Although no clinical trials have assessed the effectiveness of aural toilet alone,⁴⁰ without the wick and adequate cleaning of the canal, the topical drops may not achieve adequate penetration and are ineffective. Available options for topical therapy include multiple topical antibiotics, antiseptics, steroids, and combination agents.^{13,27,60,64} Topical antimicrobial therapy

FIG. 15.1 Patient with acute otitis externa, with purulent drainage from the ear canal and mild edema and erythema of the pinna.

BOX 15.2 Common Pathogens in Otitis Externa

Gram-Negative Organisms

Pseudomonas aeruginosa
Pseudomonas spp. Nov. "otitidis"
Proteus mirabilis
Serratia marcescens

Gram-Positive Organisms

Staphylococcus aureus
Staphylococcus epidermidis
Corynebacterium auris
Enterococcus faecalis

Fungi and Yeasts

Aspergillus fumigatus
Candida albicans
Candida parapsilosis

increased absolute clinical cure rates of acute otitis externa by 46% and bacteriologic cure rates by 61% in contrast to placebo.⁶⁴ Freedman²⁸ compared topical neomycin/colistin/hydrocortisone with topical placebo and found less severe edema and itching by day 3 and less severe edema, itching, redness, scaling, and weeping by day 7.⁶⁴ Without treatment, only 15% of patients with acute otitis externa have clinical cure within 10 days; however, the cure rate increases to 65% to 85% when topical antimicrobial therapy is administered.^{28,64}

Rosenfeld and colleagues⁶⁴ performed a meta-analysis to assess topical antiseptics and antibiotics and found comparable clinical cures at 7 to 14 days. The most common antiseptics used in the treatment of otitis externa include acetic acid, boric acid/ethyl alcohol and aluminum acetate, and *N*-chlorotaurine. Acetic acid and aluminum acetate solution at pH 3.0, commonly known as modified Burow solution, has been found to inactivate in vitro *Pseudomonas* spp., gram-positive organisms (including MRSA, but excluding *Enterococcus*), and *Candida albicans* within 5 minutes and all gram-negative bacteria within 20 minutes.³⁹

Topical antibiotic preparations usually are divided into two groups: quinolones and nonquinolone antibiotics. Nonquinolone antibiotics, such as polymyxin, neomycin, gentamicin, tobramycin, and oxytetracycline, have been the mainstay of treatment for otitis externa for several decades. Most of these agents have some degree of ototoxicity, however, which renders them undesirable in the case of a tympanic membrane perforation or a patent pressure-equalizing tube.^{45,57} The introduction of quinolones in the late 1980s for management of otitis externa and necrotizing external otitis provided a nonototoxic alternative treatment. Topical antibiotic therapy allows for the administration of high concentrations of antibiotics, which can overcome organisms with high minimal inhibitory concentrations. Rosenfeld and colleagues⁶⁴ reported comparable clinical cure rates for topical quinolone antibiotics compared with nonquinolones at 3 to 4 days, 7 to 10 days, and 14 to 28 days. This same study found no differences in adverse effects between the two antibiotic groups.

One of the most common mistakes in the treatment of otitis externa is not identifying a tympanic membrane perforation and draining middle ear as the source of the infection, which may have treatment implications because of the ototoxicity of some compounds.

Typical duration of topical treatment is 7 to 10 days. Patients with more severe infections may require 10 to 14 days of treatment. It is commonly recommended that drops be given for 3 days beyond the cessation of symptoms.⁷⁰

Oral antibiotics are not routinely indicated for the treatment of otitis externa. A clinical trial by Roland and colleagues⁵⁹ comparing oral antibiotic plus antibiotic/steroid drop versus antibiotic/steroid drop showed that a single topical agent is equivalent to combination of topical and oral antibiotic treatment for otitis externa and has similar clinical outcomes.

Indications for systemic antibiotics in acute otitis externa are few and include complicated infection by associated cellulitis of the surrounding skin or other underlying conditions (e.g., diabetes or immunosuppression).⁴⁰ In spite of increasing awareness of inappropriate antibiotic use and its implications, prescription of systemic antibiotics in the outpatient setting remains frequent and has experienced only a modest decrease (about 4.9%) over the past few years.²³ Up to 40% of patients are prescribed systemic antibiotics in addition to or instead of topical therapy, many of which are not active against *P. aeruginosa* or *S. aureus*, the most common pathogens associated with otitis externa.^{23,33,66} Use of systemic antibiotics can only be justified when there is a concomitant diagnosis of otitis media or regional spread of infection. Oral antibiotics, when not appropriately prescribed, increase treatment cost, potential side effects, and likelihood of noncompliance and are more likely to contribute to emergence of antimicrobial resistance than is topical antimicrobial therapy. An evidence-based review concluded that no significant topical antibiotic resistance develops from the use of ototopical antibiotic treatment alone.⁸³

CHRONIC OTITIS EXTERNA

Chronic otitis externa is an inflammatory condition of the ear canal skin, with symptoms lasting from 6 weeks to more than 3 months. This

condition generally is caused by the loss of the protective coating of cerumen and oils secondary to constant mechanical debridement, such as with cotton applicators or repeated water exposure. Associated pruritus leading to self-cleaning perpetuates the vicious cycle. The ear canal with chronic otitis externa often is more vulnerable to bacterial superinfection.⁵⁸ *S. aureus* and *P. aeruginosa* have been shown to secrete proteases that may perpetuate pathologic skin conditions in the external auditory canal in cases of chronic otitis externa.⁴⁹ In chronic otitis externa, biofilm formation has been postulated as responsible for the pathogenesis and difficulty eradicating infection.²⁹ A shift in external ear canal pH from acidic to alkaline has been noted in patients with chronic otitis externa.⁴⁷ A subtype of chronic otitis externa is reported in 6% to 40% of patients secondary to ear canal maceration as a result of middle ear drainage after insertion of pressure equalization tubes.^{44,46,61,83}

Treatment of chronic otitis externa involves debridement and application of topical antiinflammatory agents, such as corticosteroids. Cessation of habitual canal manipulation is necessary for achieving a positive response. For severe recalcitrant cases, surgical removal of the canal skin and replacement with skin grafts may be required. Chemical peeling of canal skin also has been used in refractory cases.²⁹

OTOMYCOSIS

Otomycosis is a fungal infection of the skin of the external canal. Otomycosis often is the result of superinfection of chronic bacterial infection of the external canal or middle ear. It is often found after the use of multiple oral and ototopical antibacterial medications. All fungi have three basic growth requirements—moisture, warmth, and darkness—all of which commonly are present in the external auditory canal. The most common fungus is *Aspergillus* spp., although *Candida* spp., *Actinomyces* spp., and *Zygomycetes* also have been reported.¹¹ Pruritus is the primary clinical manifestation. Patients also complain of feeling moisture in their ears. Physical examination commonly shows a white, black, or dotted gray membrane in the external auditory canal. Diagnosis often is confirmed with a fungal culture.

Thorough cleaning with removal of the matted fungal debris and topical application of an acidifying solution, such as aluminum sulfate–calcium acetate (Domeboro), or a drying powder, such as boric acid, often is adequate treatment. Antifungals such as clotrimazole cream or solution (Lotrimin) also may be used. It is important to assess for perforation of the tympanic membrane because antifungals can be ototoxic.⁴⁵ Gentian violet usually is well tolerated in patients with mastoid cavities, but it permanently stains skin and clothing. Many patients with refractory otomycotic infections have had previous canal-wall-down mastoid surgery and require a hearing aid with a closed mold. Because the patient relies on the hearing aid virtually all day, trauma associated with placing and removing the hearing aid throughout the day can cause a significant problem. Ointments are not recommended for patients with closed hearing aids because they may promote fungal growth secondary to the accumulation of moisture.

NECROTIZING OTITIS EXTERNA

Necrotizing otitis externa is an uncommon severe infection of the external auditory canal that spreads to the surrounding subcutaneous tissues and can lead to osteomyelitis of the skull base.²⁰ This condition was described first by Chandler^{17,19} and referred to as *malignant otitis externa*; although the disease is actually benign, aggressive extension occurs, and historically it often has a poor outcome. Survival rates have improved as a result of increased awareness, allowing earlier diagnosis and treatment.^{20,21} Patients often are diabetic, immunocompromised, or undergoing postradiation therapy.^{8,69,73} Incidence of infection has been reported to be on the rise as risk factors for infection increase in the population (e.g., aging, immunosuppression, diabetes).²² The infection often begins as any other acute otitis externa involving the bony-cartilaginous junction and may extend through the fissures of Santorini to involve the parotid region. Elevation of inflammatory markers is common—in particular, the erythrocyte sedimentation rate.⁶⁸ Facial paralysis can occur as a complication of this disease and does so more commonly in children than in adults.⁵³ Facial nerve paralysis in necrotizing otitis externa often

is permanent¹⁸ and associated with more progressive disease but not with overall survival.⁷⁵ Other complications include cranial nerve palsy (X and XI),¹ subperiosteal abscess formation, mastoiditis, meningitis, and sinus thrombosis.⁴⁸

P. aeruginosa is the most common pathogen in necrotizing otitis externa. *Proteus mirabilis* also has been reported as a causal agent in some cases.^{20,21} *Staphylococcus aureus*, particularly MRSA, has been also implicated.^{35,38} Necrotizing otitis externa should be suspected in the presence of a pseudomonal infection that does not resolve and may be associated with facial nerve paralysis. The presence of granulation in the external canal at the bony–cartilaginous junction also should raise suspicion of necrotizing otitis externa. The rare reported cases of fungal malignant external otitis were due to *Aspergillus fumigatus* but a few cases associated with *Aspergillus niger*, *Scedosporium apiospermum*, *Pseudallescheria boydii*, and *Malassezia sympodialis* have been described.⁶⁷

Diagnostic imaging, including computed tomography or magnetic resonance imaging, of the temporal region often is required.³⁰ The most common finding of extension beyond the ear canal is retrocondylar fat infiltration.⁴² A positive technetium-99m scan is diagnostic for acute osteolytic osteomyelitis because it measures osteoclastic activity, but it may remain positive long after the infection has subsided. For this reason, a ^{99m}Tc scan is not ideal for monitoring treatment response.⁷⁸

Treatment of necrotizing otitis externa often involves multiple surgical debridements combined with topical and intravenous antipseudomonal antibiotics. In diabetic or immunocompromised patients, coadjuvant treatment to control the primary condition is crucial and should be initiated immediately. Transition to oral ciprofloxacin for infections with susceptible organisms has been reported with clinical improvement.³⁴ Duration of therapy is usually prolonged for at least 6 weeks and until clinical and radiographic improvement has been achieved.

Pseudomonal resistance to fluoroquinolones has been reported. Berenholz and colleagues⁹ reported 33% ciprofloxacin resistance in cases of necrotizing otitis externa. Other studies have shown strains of *S. aureus* and *S. epidermidis* that developed quinolone resistance.⁶⁰

Use of adjuvant hyperbaric oxygen also has been reported for intractable cases, but no there is no clear evidence to demonstrate its efficacy when compared with treatment with antibiotics and/or surgery.^{25,55}

DIFFERENTIAL DIAGNOSIS

Not every condition that manifests with pain and purulent discharge from the external auditory canal is otitis externa. Multiple other entities that may manifest with one or more similar symptoms include relapsing polychondritis, suppurative otitis media, and herpetic infections. In patients with suspected otitis externa who do not experience improvement after 48 to 72 hours of therapy, alternate conditions should be considered, such as noncompliance and foreign body obstruction of the canal.

Relapsing polychondritis is a progressive inflammatory disorder affecting cartilage. When it involves the ear, it usually involves the pinna and the cartilaginous portion of the external auditory canal, manifesting as swelling and erythema.⁶ This condition can affect any cartilaginous structure, including the trachea, nasal septum, and larynx. Destruction of the cartilage by inflammatory infiltrates is followed by granulation, fibrosis, and calcifications. It often is accompanied by arthralgias involving one or more joints and rarely affects only one ear.

Herpes simplex and herpes zoster also can affect the external auditory canal. Both conditions manifest with painful vesicles along the canal (Fig. 15.2) and can be accompanied by facial nerve paralysis (Ramsay Hunt syndrome or herpes zoster oticus).^{4,81} Treatment is with antivirals, such as acyclovir.

Dermatologic conditions can give the appearance of otitis externa. Allergic and contact dermatitis can manifest with erythema, weeping areas, and itching. Allergic dermatitis is a delayed hypersensitivity reaction resulting from substances such as poison ivy, rubber latex, and nickel compounds.^{51,77} Type IV cell-mediated hypersensitivity reaction to components of ototopical agents used to treat acute otitis externa has been described.⁷⁴ Treatment is administration of topical steroids and removal of the causative agent. Dermatophytid eruptions can manifest in the ear canal in response to hematogenously spread fungal by-products from a primary focus (e.g., nails, scalp, vagina).^{14,70,71,74}

FIG. 15.2 Ear canal with multiple vesicles from herpes zoster oticus.

Furunculosis is a localized form of otitis externa usually involving the outer third of the ear canal. It is characterized by abscess development in a hair follicle, with spreading of the infection to the surrounding skin. The most common causative agent is *S. aureus*. Treatment includes incision and drainage of pointing, fluctuant abscesses and application of topical antistaphylococcal antibiotics.¹⁰

Ear pain without aural drainage and external canal edema may be secondary to referred pain from the pharynx, tonsils, larynx, or teeth.

PREVENTION

Avoiding ear trauma and instrumentation, minimizing exposure of the ears to water (e.g., using ear plugs or swim caps, drying ears thoroughly after water exposure, and using alcohol-based ear drying solutions after water exposure for persons with recurring episodes of acute otitis externa), and avoiding insertion of solid objects into the ear canal are the mainstay of prevention of otitis externa.^{5,40,65,76} Additionally pool operators can help prevent transmission of *Pseudomonas* spp. and other common causes of infectious acute otitis externa in treated recreational water venues (e.g., pools, interactive fountains, and water parks) by maintaining proper chlorine and pH levels.⁸⁴

Groups at high risk for infection, particularly competitive swimmers, should be the target for educational interventions. More information on preventing swimmer's ear is available at <http://www.cdc.gov/healthywater/swimming/rwi/illnesses/swimmers-ear-prevention-guidelines.html>.

CONCLUSION

Understanding the anatomy and physiology of the external ear allows clinicians to better comprehend the natural history of the diseases that affect this region. Despite improvements in diagnostic imaging techniques, no substitute exists for a good history and physical examination to differentiate among various conditions with a similar presentation. Treatment of otitis externa should focus on achieving pain relief, meticulous cleaning of the external auditory canal, and application of topical ear drops; at the same time, clinicians should try to help prevent recurrences in patients with higher risk factors.

Otitis Media

16

Janet R. Casey • Charles D. Bluestone

Otitis media is a broad term that includes acute otitis media (AOM), otitis media with effusion (OME), chronic otitis media with effusion (COME), and chronic suppurative otitis media (CSOM). This chapter will focus on AOM and OME.

INCIDENCE AND EPIDEMIOLOGY OF ACUTE OTITIS MEDIA

AOM primarily affects children in the first 3 years of life. Onset of AOM in the first 6 months of life is not common because infants are relatively protected from infection mediated by maternal antibodies acquired transplacentally. If a child experiences AOM in the first 6 months of life, then frequent AOM episodes are likely to occur throughout the first few years of life. Most AOM occurs between the age of 6 and 24 months of age. The peak incidence is between 9 and 15 months of age. AOM does occur with modest frequency between 2 and 3 years of age but then quickly diminishes in occurrence between 3 and 5 years of age.

The occurrence of otitis media in otherwise healthy infants is partly a reflection of their immature immune system and partly due to the fact that the eustachian tube of the young child is shorter, floppier, straighter, and more horizontal than the eustachian tube of the older child. By 3 years of age, the incidence of AOM decreases because of changes in the child's anatomy and physiology and maturing immune system. Children who have had little or no otitis media by the time they reach age 3 years are unlikely to develop problems with middle ear infections later in life unless some predisposing factor, such as allergic rhinitis, tumor or fracture of the base of the skull or a facial bone, or acquired immunodeficiency, occurs.

AOM is the most common bacterial infectious disease seen in an ambulatory pediatric practice, a leading cause of health care visits, and the most frequent reason children consume antibiotics or undergo surgery.^{40,55,123} Reported AOM ambulatory visits in U.S. children younger than 2 years of age average 1244 visits per 1000 child-years,¹⁴⁴ and 80% of those visits resulted in an antibiotic prescription. AOM has a high socioeconomic impact worldwide.^{99,139} In the United States, an estimated \$4 billion is spent yearly on otitis media–related health care.^{99,144}

More recently several developments have impacted AOM incidence in the United States and worldwide. First, treatment guidelines endorsed higher dose amoxicillin for the empiric treatment of AOM due to penicillin-resistant pneumococcal infections. Second, conjugate vaccines against *Streptococcus pneumoniae*, a major pathogen of AOM, were introduced. Routine use of the 7-valent pneumococcal conjugate vaccine (PCV7) in early childhood was associated with a significant reduction in AOM visit rates as well as a decrease in pressure-equalizing tube (PET) insertion due to recurrent AOM and CSOM.^{26,43,46,56,113,128,129}

Three database analyses in three different countries demonstrated a positive effect of PCV7 on AOM episodes. Marom et al.⁸⁹ analyzed an insurance claims database of a U.S. nationwide managed health care plan. The authors showed a decreased trend in otitis media–related health care use in children younger than 6 years. Magnus et al.⁸⁶ studied children participating in the Norwegian Mother and Child Cohort Study and showed a decline of mother-reported AOM episodes in Norwegian children 12 to 18 months old and 18 to 36 months old of 14% and 8%, respectively. Using a national primary care database,⁷⁹ an observational cohort study investigated trends in AOM incidence and associated antibiotic utilization in children younger than 10 years during 2002 to 2012 in the United Kingdom. The authors found that the introduction of PCV7 was associated with a 22% reduction in AOM in children younger than 10 years and an additional 19% reduction following PCV13 introduction.

Otitis media in high-risk populations continues to be a significant medical problem. For example, epidemiologic studies from Bangladesh,¹⁴ Nigeria,³ and Australia⁹⁵ report prevalence of chronic suppurative otitis media (CSOM) of 12%, 2.5%, and 15%, respectively. Australian aboriginal children have a high rate of AOM and CSOM with tympanic membrane perforation that leads to significant long-term health impairment.⁹⁵ Native American children have a 63% incidence of AOM by 6 months of age.⁴¹ A systematic review of population-based studies from multiple countries found the highest prevalence of OM in children to be 81% of Canadian Inuits and 84% of Australian Aborigines.⁵⁷

Risk Factors

Many significant aspects of OM epidemiology and natural history were first characterized in 1960–1985. During those years it was shown that AOM risk increased according to the child's age at first AOM episode, male gender, Caucasian race/ethnicity (except in special high-risk populations noted earlier), low birth weight (<2500 g), preterm birth (<37 weeks' gestation), fall season of birth, bottle-feeding, daycare attendance, higher number of young siblings, lower parent's education/income/occupation, more frequent history of ear infections (plus other infectious illnesses or conditions) in siblings or parents, absent or poor health insurance coverage, and exposure to secondhand cigarette smoking.^{5,6,8,9,12,13} Table 16.1 shows results of a meta-analysis of risk factors for chronic AOM and recurrent AOM.¹⁴³

Microbiology of Acute Otitis Media in the Pneumococcal Conjugate Vaccine Era

The bacteria that cause AOM vary from country to country due to vaccination and antibiotic prescribing habits because these preventative and therapeutic interventions impact the otopathogens that predominate

TABLE 16.1 Risk Factors for Acute Otitis Media Development (Pooled Analysis)

Risk Factor	Odds Ratio	95% Confidence Interval
Allergy/atopy	1.36	1.13–1.64
Upper respiratory infection	6.59	3.13–13.89
Chronic nasal obstruction	1.19	0.84–1.69
Snoring	1.96	1.78–2.16
Male gender	1.24	0.99–1.54
Daycare center attendance	1.70	0.95–3.05
Family history of otitis media	1.40	0.86–2.28
Patient history of AOM/rAOM	11.13	1.06–116.44
Passive smoke exposure	1.39	1.02–1.89
Low socioeconomic status	3.82	1.11–13.15
Low education level of mother	1.68	0.32–8.68
Mother’s smoking during pregnancy	2.34	0.64–8.54
Multiple siblings	1.57	0.93–2.63
Breastfeeding >6 mo	0.57	0.17–1.93
Any breastfeeding	0.91	0.47–1.79

rAOM, Recurrent acute otitis media.
Modified from Zhang Y, Xu M, Zhang J, et al. Risk factors for chronic and recurrent otitis media—a meta-analysis. *PLoS One*. 2014;9(1):e86397.

FIG. 16.1 Acute otitis media otopathogen distribution 1995–2014. *Mcat*, *Moraxella catarrhalis*; *NTHi*, nontypeable *Haemophilus influenzae*; *PCV*, pneumococcal conjugate vaccine; *Spn*, *Streptococcus pneumoniae*. (Data from Casey JR, Pichichero ME. Changes in frequency and pathogens causing acute otitis media in 1995–2003. *Pediatr Infect Dis J*. 2004;23:824–8; Casey JR, Adlowitz DG, Pichichero ME. New patterns in the otopathogens causing acute otitis media six to eight years after introduction of pneumococcal conjugate vaccine. *Pediatr Infect Dis J*. 2010;29:304–9; and Casey JR, Kaur R, Friedel VC, Pichichero ME. Acute otitis media otopathogens during 2008 to 2010 in Rochester, New York. *Pediatr Infect Dis J*. 2013;32:805–9.)

in the nasopharynx before ascending via the eustachian tube to the middle ear space. In most developed countries virtually all children are vaccinated with the PCV7 or PCV13, discussed later in this chapter. Most children are treated with antibiotics, predominantly amoxicillin in a standard dose (40 mg/kg per day divided twice daily) or a “high” dose (80 mg/kg per day divided twice daily) for 10 days. As a consequence of PCV and amoxicillin use, the etiology of AOM continues to change over time. The dynamic changes in the otopathogen mix from 1996 to 2015, based on tympanocentesis isolations from the Rochester, New York, otitis media research center are shown in Fig. 16.1.²⁴

S. pneumoniae caused approximately 30% to 60% of episodes before the PCV era. Following the introduction of PCV7, *S. pneumoniae* as a

TABLE 16.2 Otopathogen Distribution Causing Acute Otitis Media in Rochester, NY, 2008–10

Year	Total Visits	Otopathogen Isolated From MEF	No. (%)
2008	57	<i>S. pneumoniae</i>	18 (32)
		Nontypeable <i>H. influenzae</i>	16 (28)
		<i>M. catarrhalis</i>	10 (18)
2009	78	<i>S. pneumoniae</i>	32 (41)
		Nontypeable <i>H. influenzae</i>	18 (23)
		<i>M. catarrhalis</i>	14 (18)
2010 (until September 30)	73	<i>S. pneumoniae</i>	21 (29)
		Nontypeable <i>H. influenzae</i>	25 (34)
		<i>M. catarrhalis</i>	5 (7)

MEF, middle ear fluid.
Modified from Casey JR, Kaur R, Friedel V, Pichichero ME. Acute otitis media otopathogens during 2008 to 2010 in Rochester, New York. *Pediatr Inf Dis J*. 2013;32(8):805–9.

cause of AOM decreased in frequency, and nontypeable *Haemophilus influenzae* AOM increased proportionately. Two years after PCV7 introduction, *S. pneumoniae* began to increase proportionately due to nonvaccine serotypes, dominated by serotype 19A.^{39,47,48,53,64,107} There was complete elimination of PCV7 serotypes and replacement with nonvaccine serotypes in the nasopharynx^{36,78,90,98,104,135,138} and as a cause of AOM in the countries using PCV7.^{15,21,24,26} The otopathogens causing AOM in young children in 2008 to 2010, the late PCV7 era in the Rochester otitis media research center, are shown in Table 16.2 and Fig. 16.1. After licensure of PCV13, a prompt transition from PCV7 to PCV13 occurred in 2010 in the United States. A decrease in nasopharyngeal colonization caused by *S. pneumoniae* serotypes 6A and 19A followed.^{37,67,85,118,130} A decline in *S. pneumoniae* and a proportional increase in nontypeable *H. influenzae* and *M. catarrhalis* AOM occurred (Fig. 16.1). Pneumococcal otopathogens from the middle ear cultures from children from 2011 to 2013 showed a significant decrease in PCV13 serotypes and in penicillin-resistant isolates. The most common non-PCV13 serotypes were 35B; 21; 23B; 15A, B, C; 11; and 23A.⁶⁷

Pneumococcal AOM in children younger than 2 years has been studied following the sequential introduction of PCV7 and PCV13. In the PCV7 era in Israel there was a 77% decline in pneumococcal AOM episodes. In the post-PCV13 era, there was a 51% decline in PCV13 serotypes, and the most common non-PCV13 serotypes isolated from middle ear fluid (MEF) were 15B/C, 16F, and 35B.¹¹ Overall the trend in AOM cases has declined since the introduction of PCVs according to other reports in the United States, the United Kingdom, and Israel.¹³⁴ In 2015, *M. catarrhalis* became the most common cause of AOM in the Rochester otitis media research center.²⁵

Etiology in Neonates

Other than the more frequent occurrence of disease caused by gram-negative enteric organisms (approximately 20% of cases) and the occasional isolation of other neonatal pathogens (e.g., group B streptococci), the bacteriology of otitis media in this age group is similar to that in older children.

PATHOPHYSIOLOGY

Tympanic Membrane

As inflammation develops in the middle ear space, changes in the tympanic membrane occur rapidly. The presence of congested blood vessels, edema (which obscures normal landmarks), and bulging occurs, indicating not only a myringitis (inflammation of the tympanic membrane) but also the presence of fluid under pressure in the middle ear space. Sometimes blebs appear on the surface epithelium as a consequence of AOM and the heat of the inflammatory process (most often associated with group A streptococcal infections of the middle ear).

Inflammation may occur on outer epithelial or inner mucosal sides of the fibrous layer (middle layer) of the tympanic membrane. In severe cases, infection may involve the fibrous layer itself. The membrane thickens as a result of edema and infiltration of polymorphonuclear leukocytes. All three layers of the tympanic membrane may undergo dissolution owing to pressure necrosis resulting from the expanding middle ear abscess or thrombophlebitis of tympanic veins, with resulting perforation. With evacuation of the contents of the middle ear abscess after perforation or therapeutic tympanocentesis, healing may be rapid, and the perforation usually seals within a few days. In the process of healing, scar formation may occur.

Occasionally, when a perforation is close to the margin of the annulus or occurs in the Shrapnell membrane, the skin of the external auditory canal and the surface squamous epithelium of the tympanic membrane may grow through the aperture and invade the middle ear. This event may lead to formation of a cholesteatoma (epidermal inclusion cyst). Even if the perforation heals, a differential in gas pressure across the tympanic membrane caused by malfunction of the eustachian tube may result in resorption of gas in the middle ear cavity and negative pressure in the middle ear, which causes retraction of the Shrapnell membrane or an atrophic scar into the middle ear or mastoid attic.

Eustachian Tube

The eustachian tube is approximately 3.8 cm long in an adult. It opens in the fossa of Rosenmüller and extends upward, backward, and laterally to open in the upper anterior wall of the tympanic cavity (protympanum). At birth, the eustachian tube is immature; that is, it is much shorter and floppier than at 1 year of age. It is composed of two portions: the cartilaginous portion extending into the nasopharynx and the bony portion originating in the middle ear. The upper third of the tube is bony; the middle ear opening is the widest, and the medial end (the part joining the cartilaginous eustachian tube), or isthmus, is the narrowest. Pneumatic peritubal air cells arising from the middle ear cavity surround it and can extend to the petrous apex. The internal carotid artery courses anteromedial to this region.

The lower two-thirds of the eustachian tube is a narrow, slit-like, fibrocartilaginous passage. It makes a 160-degree angle with the bony portion at its junction.

Three muscles are associated with the eustachian tube. The tensor tympani muscle lies on top of it; the levator veli palatini muscle lies under it; and the tensor veli palatini muscle arises on the tube, scaphoid fossa, and spine of the sphenoid and then courses around the hook of the hamulus and forms an aponeurosis with its mate (from the opposite side) in the soft palate. This muscle is the only one that acts directly on the eustachian tube.¹⁶

The eustachian tube area, protympanum, and hypotympanum are lined by ciliated columnar epithelium with goblet cells or secretory cells. The epithelium is continuous with the upper airway system and paranasal sinuses. This area also contains a well-defined subepithelial connective tissue layer, which thins out and may be absent nearing the antrum and mastoid air cell system. The movement of the cilia and mucous blanket always is toward the eustachian tube and nasopharynx. The tube is surrounded by a plexus of lymphoid channels. It has an arterial supply from a branch of the middle meningeal or accessory meningeal artery and from branches of the artery of the pterygoid canal. The nerve supply is from the tympanic plexus (ninth cranial nerve; sensory) and sphenopalatine ganglion (sympathetics and parasympathetic palatine fiber).

The bony portion is rigid and patulous; the medial two-thirds normally is held closed by elastic recoil of the fibrocartilaginous tissue. Contraction of the tensor palatini muscle that inserts in the anterolateral wall opens the tube on swallowing. On average, an adult swallows once per minute while awake and once every 5 minutes while asleep. Suckling infants usually swallow five times per minute.

Mucus and ciliary action flow from the middle ear to the eustachian tube. The eustachian tube acts as a unidirectional valve that favors outflow from the middle ear to the pharynx. Reverse flow can be induced by an increase in pressure in the nasopharynx (Valsalva, barotrauma). During occlusion of the eustachian tube, oxygen and carbon dioxide (and other gases) are absorbed from the middle ear by diffusion into

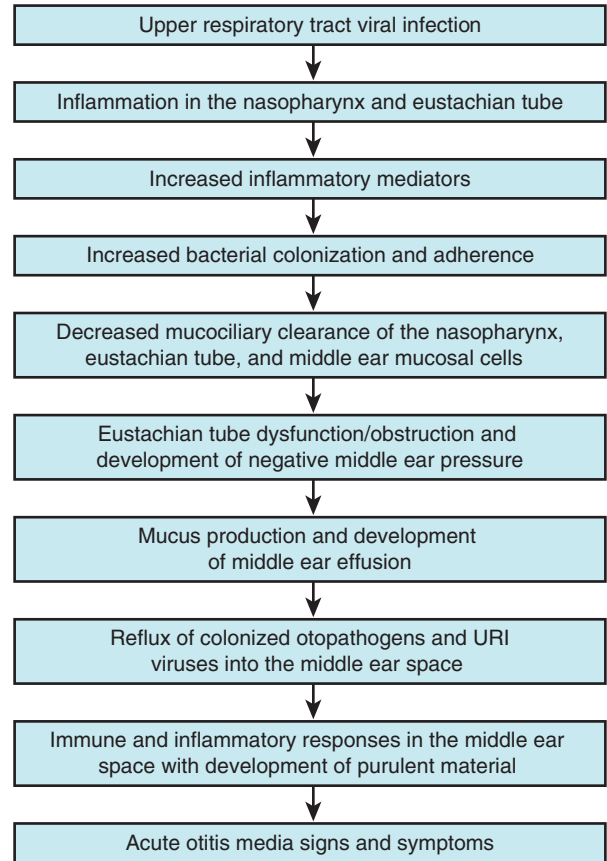

FIG. 16.2 Pathogenesis of virus-induced acute otitis media. *URI*, Upper respiratory infection.

the rich vasculature, and a negative pressure is created. A patent eustachian tube is a crucial prerequisite for subsidence of middle ear disease.

PATHOGENESIS

Approximately 35% of upper respiratory infection (URI) episodes are complicated by AOM, which occurs usually within the first week of URI onset, and 90% to 95% of children with AOM have concurrent URI symptoms.^{32,66} Disease etiology and pathogenesis are complex and begin with colonization of mucosal surfaces in the upper respiratory tract by potential AOM bacterial pathogens (Fig. 16.2). In order to colonize the nasopharynx, otopathogens must first compete with each other and with commensal bacteria in the nasopharynx. Nontypeable *H. influenzae* outcompetes *S. pneumoniae* (except serotype 19A) and *M. catarrhalis* for higher rates of colonization during AOM. The combination of respiratory bacteria, *S. pneumoniae*, nontypeable *H. influenzae*, and *M. catarrhalis*, colonizing the nasopharynx and the introduction of a viral URI results in complex interactions that set the stage for the development of AOM.^{105,121,142}

Viral URI sets the stage for AOM and OME by increasing mucus production, slowing the beat of cilia in the nasopharynx, creating an inflammatory environment in the nasopharynx, and downregulating the innate and adaptive immune response (discussed later in the section “Immunology”). Next the eustachian tube closes due to inflammation caused as part of the viral URI process. Negative pressure builds in the middle ear space as the air diffuses across the tympanic membrane, resulting in a retracted tympanic membrane. The middle ear goblet cells produce mucus to keep the surface of the middle ear cells moist, and, with the eustachian tube closed, the mucous builds up and causes fluid to be visible behind the tympanic membrane. This is OME. However, when OME develops, the middle ear is still sterile, and the absence of

FIG. 16.3 Otitis media continuum. Area above the horizontal line represents positive pressure, bulging, or fullness of the tympanic membrane. Area below the horizontal line represents negative pressure or a retracted tympanic membrane. AOM, Acute otitis media; MEE, middle ear effusion; OME, otitis media with effusion; TM, tympanic membrane; URI, upper respiratory infection. (Modified from Pichichero ME. Acute otitis media: part II. Treatment in an era of increasing antibiotic resistance. *Am Fam Physician*. 2000;61:2051–56.)

a virus or bacteria and an inflammatory process results in the tympanic membrane remaining generally translucent. Fig. 16.3 shows the continuation of OME and AOM.

As the negative pressure develops in the middle ear space, the secretions in the nasopharynx are literally sucked into the middle ear space when the eustachian tube temporarily relaxes for a part of a second. Once the secretions and accompanying virus and bacteria that were in the nasopharynx gain entry to the middle ear space, the environment is free of immune-controlling factors, and the bacteria begin to divide. In response to the local bacterial invasion, the innate immune response is activated, resulting in the influx of neutrophils. The neutrophils release mediators of inflammation, and the health care provider observes that pathogenic process when glimpsing a tympanic membrane that has become thickened with edema, perhaps red, but most important bulging from the pressure of an inflammatory response (see the section “Clinical Manifestations and Diagnosis”).

Bacterial otopathogens and respiratory viruses interact and play important roles in AOM development.^{96,105,117} However, much confusion surrounds the role of URI viruses as an etiology of AOM and OME. While there is no doubt that viral URI plays a key role in the pathogenesis of AOM and OME, the role is more facilitation of bacterial AOM than a primary etiologic role for these viruses (see the section “Immunology”).⁵⁹ Respiratory syncytial virus (RSV), influenza, parainfluenza, rhinovirus, metapneumovirus, and other viruses can be detected in the nasopharynx secretions of children with URI followed by AOM. The nasopharynx secretions can reflux from the nasopharynx via the eustachian tube into the middle ear space, so the detection of the virus in MEF by tympanocentesis does not confirm that virus is the etiology of AOM. With modern polymerase chain reaction (PCR) techniques, the DNA or RNA of viruses can be detected in the nasopharynx and MEF of many children with AOM and OME.^{33,60,97,141} The presence of a respiratory virus without a bacterial otopathogen simultaneously detected is uncommon, probably around 2% to 10% of all cases of AOM.^{31,116}

OME can persist for some time after an AOM. About half of children who experience AOM will have OME 1 month after initial diagnosis, one-third have OME 2 months after AOM, and 10% have OME 3 months after AOM (Fig. 16.4).

DIAGNOSIS

Symptoms and Clinical Manifestations of AOM

Symptoms associated with AOM and its complications and sequelae include the following:

1. Otalgia, or ear pain, is the most common feature of infants and children with AOM. The symptom is suggested in young infants

FIG. 16.4 Persistence of middle ear effusion after onset of acute otitis media. (Modified from Teele DW, Klein JO, Rosner BA. Epidemiology of otitis media in children. *Ann Otol Rhinol Laryngol*. 1980;89:5–6.)

who are pulling at the ear or excessively irritable. Some infants do not have earache.

2. Otorrhea is drainage from the middle ear through a perforation in the tympanic membrane. Relief of the pressure on the tympanic membrane results in immediate decrease in pain. Because the tympanic membrane has a dense network of blood vessels, rapid repair of the membrane occurs, and the perforation usually closes within 24 to 72 hours. If the tympanic membrane seals and the infection still is present, fluid may reaccumulate with renewed acute signs of AOM.
3. Hearing loss occurs whenever fluid fills the middle ear space, whether the fluid is associated with acute infection or with OME. When fluid fills the middle ear space, the median hearing loss is 25 dB (the equivalent of having plugs in the ear canals).
4. Vertigo is not a common complaint of children with AOM. Vertigo occurs more commonly in unilateral than bilateral disease and may be caused by labyrinthitis. Older children describe a feeling of spinning, whereas younger children may not be able to verbalize these symptoms but manifest disequilibrium by falling or stumbling.
5. Tinnitus is an uncommon complaint in children, but when it does occur, the symptom often is caused by OME and eustachian tube dysfunction.
6. Swelling around the ear, especially in the postauricular area, may be a sign of mastoiditis.

7. Facial paralysis in children occurs as a complication of AOM or chronic otitis media with perforation of the tympanic membrane or as a result of an enlarging cholesteatoma.
8. Conjunctivitis has been associated with AOM because the organisms that cause AOM originate in the nasopharynx and may simultaneously cause AOM and conjunctival infection.

There is ample evidence to confirm that the diagnosis of AOM cannot rely on clinical manifestations. Upper respiratory viral infections and AOM occur simultaneously and share many nonspecific symptoms. Table 16.3 shows the sensitivity and specificity of a number of symptoms young children have at the time of evaluation for possible AOM. Parents who suspected that their child aged 6 to 35 months old had AOM were correct only half of the time when the clinicians used strict otoscopic criteria. Half had a URI but no AOM. Ear pain, ear rubbing, fever, irritability, restless sleep, and severe or prolonged rhinitis/cough does not increase the probability of AOM.⁷⁷

AOM symptom scoring scales have been developed to aid in the diagnosis of AOM, to assign severity scores, and to assist in the evaluation

of response to treatment or watchful waiting in young children with AOM. Table 16.4 shows AOM scoring systems and the items assessed. A 3-item score (OM-3),¹¹⁹ consisting of physical symptoms including ear pain, fever, emotional distress (irritability or poor appetite), and limitation in activity, and a 5-item score (Ear Treatment Group Symptom Questionnaire, 5 Items; ETG-5), including fever, earache, irritability, decreased appetite, and sleep disturbance, have been validated. A parental assessment of symptom severity using a visual scale of faces, Acute Otitis Media–Faces Scale (AOM-FS),¹¹² also has been developed. None of these three scales was adequately sensitive for making the diagnosis of AOM based only on symptoms. However, the OS-8 scale,^{91,92} consisting of a set of tympanic membrane photographs that the clinician could use to grade the severity of tympanic membrane inflammation and combined with the faces scale (OM-FS) to assess the parental perception of severity of symptoms, was able to show changes in the child's symptoms and signs of AOM.⁵⁰ Another validated scale included a 7-item parent-reported symptom score (Acute Otitis Media Severity of Symptom Scale–AOM-SOS) for children with AOM to aid in assessing patient-reported outcome measures during clinical trials. Symptoms included ear tugging/rubbing/holding, excessive crying, irritability, difficulty sleeping, decreased activity or appetite, and fever. The AOM-SOS scale, when compared with otoscopic diagnoses (AOM, OME, and normal), showed that it, too, changed in response to clinical improvement or deterioration similar to the OS-8 scale.^{124,125}

A 30-point symptom scoring instrument (Otitis Media Clinical Severity Index, OM-CSI) was developed to determine the severity of AOM and to measure the treatment outcome of AOM in young children.³⁸ A shorter, easier-to-use 10-point scoring instrument was developed and compared to the 30-point scoring instrument; both the 10-point and 30-point scoring systems were able to measure treatment outcome and differentiated between clinical cure and failure at the follow-up test-of-cure visit.²³

Diagnostic Signs of Acute Otitis Media

AOM is a visual diagnosis based on viewing the tympanic membrane. The accurate diagnosis of AOM in infants and young children can be difficult. Having the proper equipment and the proper positioning of the child are critical to achieve the correct diagnosis. It is not possible to diagnose AOM accurately without complete visualization of the tympanic membrane. A glimpse of a small portion of the tympanic membrane is not sufficient to make the diagnosis of AOM. It is recommended that the clinician take the time and make the effort to clear

TABLE 16.3 Sensitivity and Specificity of Symptoms' Ability to Predict Acute Otitis Media

Symptoms	Sensitivity (%)	Specificity (%)
Cough	47–84	45–83

FIG. 16.5 The correct positioning of a child on the parent's lap. This position allows the child to feel secure and allows clear access to examine the ear.

all or nearly all of the ear canal cerumen, use optimal lighting, and use the largest ear speculum that can fit snugly into the child's ear canal so that a seal can be made for pneumatic otoscopy.

EXAMINATION OF THE EAR

Otосcopy

Examination of the ear should begin with observation of the auricle and the external auditory meatus. Palpation of the periauricular areas should be done to indicate presence of periostitis or diffuse external otitis. The ear canal should be examined for inflammation or cerumen that obstructs vision of the tympanic membrane. Proper positioning of the child for optimal examination of the tympanic membrane is shown in Fig. 16.5.

For proper assessment of the tympanic membrane and its mobility, a pneumatic otoscope in which the diagnostic head has a secure seal should be used. The speculum should have the largest lumen that can fit comfortably into the child's cartilaginous external auditory meatus (Fig. 16.6). The important landmarks of the tympanic membrane that can be visualized with the otoscope are indicated in Fig. 16.7.

The otoscopic examination should include observation of the following conditions of the tympanic membrane:

- **Position:** Normal is slightly convex; bulging indicates increased pressure from positive air pressure or fluid; a retracted eardrum indicates negative pressure with or without effusion; fullness of the tympanic membrane is apparent initially in the posterosuperior portion of the pars tensa and the pars flaccida because these two areas are the most highly compliant parts of the membrane.
- **Appearance and color:** The normal color is pearly gray and translucent; any congestion of the mucous membrane of the middle ear would be reflected in congestion of the vessels of the tympanic membrane and appear pink; a blue discoloration suggests blood in the middle ear associated sometimes with basal skull fracture; the inflamed middle ear mucosa usually is reflected in a bright red tympanic membrane.
- **Integrity of the membrane:** All four quadrants of the tympanic membrane should be inspected for presence or absence of perforation, retraction pockets, or cholesteatoma.
- **Mobility:** Application of positive and negative pressures by the pneumatic otoscope enables the viewer to determine the presence

FIG. 16.6 Macroview pneumatic otoscope. (Courtesy Welch Allyn.)

FIG. 16.7 Normal tympanic membrane with normal landmarks identified.

of an air-filled space (rapid movement of the membrane on positive and negative pressures) or a fluid-filled space (limited or no movement of the membrane). Fig. 16.8 shows a normal tympanic membrane, a retracted tympanic membrane, and a bulging tympanic membrane.

In 2013 the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP) released a revision and update of their 2004 AOM guidelines.⁸¹ The 2013 updated guidelines used a more stringent diagnostic definition of AOM. Bulging of the tympanic membrane was emphasized as the most specific otoscopic sign of AOM. Three studies evaluated otoscopic signs—position, color, mobility of the tympanic membrane—and correlated the signs with the presence of middle ear effusion⁶⁸ or the isolation of an otopathogen^{58,93} following myringotomy or tympanocentesis. Karma et al.⁶⁸ looked at the tympanic

FIG. 16.8 (A) Normal tympanic membrane with a neutral position, pearly gray in color and translucent. Normal landmarks are easily visible. (B) Otitis media with effusion: a retracted tympanic membrane with a very prominent head of the malleolus, gray/yellow in color and semiopaque, with air-fluid level and air bubble visible. (Courtesy Dr. Hoberman, University of Pittsburgh.)

membrane physical findings of color, position, and mobility in children with and without acute symptoms suggestive of AOM. Of all the tympanic membrane characteristics, a bulging tympanic membrane reliably predicted the presence of middle ear effusion. Halsted et al.⁵⁸ described the likelihood of a positive tympanocentesis culture given different tympanic membrane characteristics. The authors found a positive bacterial culture in 91% of children who had a bulging tympanic membrane, in 21% with a minimally bulging or full tympanic membrane, and in 0% of children without a bulging tympanic membrane. Last, McCormick et al.⁹² studied the association between certain signs and symptoms of AOM and the presence of bacterial or viral isolates from middle ear fluid. The authors concluded that the single most important clinical feature associated with a pathogen was fullness and bulging of the tympanic membrane. In all these studies, erythema or lack of mobility of the tympanic membrane was less likely to be associated with middle ear effusion or the isolation of a bacterial pathogen from the middle ear fluid. From those and other studies the key diagnostic feature of AOM was established as a bulging or full appearance to the tympanic membrane (Fig. 16.8C). The bulging of the tympanic membrane is due to positive pressure behind the tympanic membrane caused by inflammation in the middle ear space. AOM is not associated with a retracted tympanic membrane, so a determination of retraction of the tympanic membrane is a viral-mediated phenomenon or associated with OME (Fig. 16.8B). A bulging compared to a retracted tympanic membrane can be difficult to distinguish. Use of pneumatic otoscopy is very helpful in distinguishing the two because positive pressure on insufflation will result in movement backward by a bulging tympanic membrane, and negative pressure will result in movement forward by a retracted tympanic membrane.

Because of the inflammation in the middle ear space during AOM, the tympanic membrane becomes thickened and semi-translucent or completely opaque. A translucent tympanic membrane is very unlikely to be associated with AOM. A translucent or semi-translucent tympanic membrane and middle ear fluid visualized behind the tympanic membrane point to a likely diagnosis of OME (see Fig. 16.8).

Redness of the tympanic membrane is not considered a valuable diagnostic sign of AOM. Redness occurs from inflammation, but a red tympanic membrane can also occur from fever or from a crying child (and most children of the age who experience AOM cry during the examination). When an otoscope speculum is inserted into the external auditory canal, the tympanic membrane will sometimes turn red. The presence of one red tympanic membrane and the other tympanic membrane not red suggests inflammation of the tympanic membrane and is consistent with the diagnosis of AOM if there is fluid visualized behind the tympanic membrane. Such an examination most likely represents an early AOM before inflammation has persisted long enough

to cause the tympanic membrane to become thickened and more yellowish and opaque.

OME is not associated with inflammation; however, a child with OME may feel discomfort and may feel popping as air gains entry via the eustachian tube into the middle ear space as well as hearing loss. This may cause the child to pull and tug at the ear or even cry. But the visual examination is distinct from AOM, as just outlined. Fig. 16.9 shows the transition from OME to AOM.

Tympanometry

The tympanogram identifies the movement of the tympanic membrane in response to positive and negative pressure. It utilizes the concept that sound energy in a closed space is diluted or concentrated as the volume increases or decreases (Fig. 16.10). The movement or compliance of the tympanic membrane that occurs following a pulse of air pressure is recorded graphically. The device sweeps pressure from 200 dekapascals (daPa, a unit of pressure equal to 1.04 mm of water) to –300 to 600 daPa. A number of different curves are generated by the tympanometer depending on the state of the middle ear and the patency of the tympanic membrane. A sharply peaked curve with maximum compliance at normal pressure is designated as an A curve and is usually seen with a normal tympanic membrane and middle ear space. A flat curve, referred to as a B curve, is found when there is no movement of the tympanic membrane, when the middle ear is full of fluid, or when there is a perforation of the tympanic membrane. A curve with a peak that occurs at an abnormal amount of negative pressure is referred to as a C curve. A C curve is often seen when there is negative pressure within the middle ear space and the tympanic membrane is retracted (Fig. 16.11). In some cases, the tympanic membrane will be full or bulging, and the tympanic reading is then called a *positive pressure tympanogram readout*. Tympanometry requires a complete seal of the inserted speculum-like device in the external auditory canal and a few seconds of patient cooperation. Children younger than 2 years of age, when AOM is most common, often move, and a seal cannot be obtained. Also if a child is crying a tympanogram reading cannot be obtained.

Acoustic Reflectometry

Spectral gradient acoustic reflectometry (SGAR) has been validated as an accurate method of testing for middle ear effusion in children and infants older than 3 months of age (Fig. 16.12). An 80-dB spectrum of sound, 1.6 to 4.7 kHz, is emitted from the device and directed toward the tympanic membrane. The device measures the sum of the reflected sound energy. A normal tympanic membrane and air-filled middle ear space absorb the majority of the sound, and very little acoustic energy reflects back to the device, giving a high numeric readout. If the sound waves hit a thickened tympanic membrane and fluid in the middle ear

FIG. 16.9 Transition from normal to otitis media with effusion (OME) to acute otitis media. (A) Normal tympanic membrane with pearly gray translucent appearance. (B) OME with air bubbles. (C–D) OME fully filled with effusion; note retracted and translucent tympanic membrane with prominent head of the malleus. (E) Slight bulging with semiopaque white tympanic membrane. (F) Bulging semiopaque tympanic membrane. (G) Marked bulging, donut appearance, opaque, white tympanic membrane. (H–I) Severe bulging with bullae formation. (Courtesy Dr. Hoberman, University of Pittsburgh.)

space, less sound is absorbed and more sound is reflected back to the device, giving a lower numeric readout. This instrument does not require a seal in the external auditory canal, and readings can be obtained in the crying child. The main limitation is the presence of cerumen in the external auditory canal.

A comparison of tympanometry and SGAR in the ability to assess the presence of middle ear effusion using pneumatic otoscopy as the gold standard showed an agreement between the two methods of 86%. The detection of middle ear effusion by tympanometry and SGAR compared to diagnosis by pneumatic otoscopy showed excellent agreement.¹¹⁵ Table 16.5 shows the percentage of ears with middle ear effusion documented by pneumatic otoscopy versus the level of SGAR. SGAR instruments detected middle ear effusion with 67% sensitivity and 87% specificity and performed similarly to pneumatic otoscopy.¹⁷ The ease

of use, easy portability, absence of need for an airtight seal, and low cost make the use of SGAR an excellent aid in the diagnosis of middle ear effusion.

Audiometric Testing

When fluid is present in the middle ear space, it can cause diminished hearing. An audiogram can assist in establishing the extent of hearing loss for both AOM and OME. Testing the hearing of young children is difficult in clinical settings other than audiology practices that can utilize brainstem evoked responses. Thus, although a potentially useful tool to quantify hearing loss, audiometry is not often used in the first few years of life when AOM and OME most frequently occur. This paradox is problematic for compliance with national recommendations for management of OME, where the presence of unilateral hearing loss

of 6 months' duration or bilateral hearing loss of 3 months' duration to greater than 30-decibel thresholds in the speech range (500–2000 Hz) is a primary criterion for the recommendation of insertion of tympanostomy tubes.

Tympanocentesis and Myringotomy

Tympanocentesis, a needle aspiration of the middle ear effusion, is used primarily for establishing the presence or absence of an effusion and for microbiologic diagnosis. The 2013 AAP/AAFP AOM guidelines endorse the use of tympanocentesis in the hands of a person skilled in the procedure for treating children with recurrent AOM or treatment failure. Because cultures of the upper respiratory tract are of limited value in providing specific microbiologic diagnosis of AOM, only bacterial cultures obtained by aspiration of the middle ear abscess can be considered a true reflection of the etiology of AOM.^{72,137}

Myringotomy is an incision in the anterior lower quadrant of the tympanic membrane for therapeutic drainage. Tympanocentesis or myringotomy should be considered in patients who at onset of AOM

FIG. 16.11 Tympanogram curves. (Top) Normal tympanogram. Normal tympanic membrane compliance; normal tympanic membrane; no middle ear disease. (Middle) Abnormal tympanogram. Decreased compliance of the tympanic membrane; middle ear effusion (otitis media with effusion or acute otitis media). (Bottom) Abnormal tympanogram. appear toxic or are seriously ill, in patients who are not clinically responding after initiation of empiric antimicrobial therapy, in the presence of suppurative complications (including mastoiditis and meningitis), in immunologically deficient patients in whom an unusual organism may be present, and for recurrent AOM in the otitis-prone child.

Radiography

Radiographic evaluation of the temporal bone is indicated when complications or sequelae of otitis media are suspected or present. Plain

FIG. 16.12 Spectral gradient acoustic reflectometer (SGAR).

radiographs are of limited value in the diagnosis of osteitis of the mastoid or cholesteatoma; computed tomography and magnetic resonance imaging are more precise and should be obtained if a suppurative intratemporal or intracranial complication is suspected.

MANAGEMENT OF ACUTE OTITIS MEDIA

In the United States the principal treatment of AOM is antibiotics, whereas in other countries watchful waiting with repeat examinations for mild AOM is the norm. Table 16.6 shows the dosing schedule for the antibiotics with an indication for the treatment of AOM. The antibiotic chosen to treat AOM should have a spectrum of activity that includes coverage of the most common otopathogens *S. pneumoniae*, nontypeable *H. influenzae*, and *M. catarrhalis* and have documented clinical and microbiologic efficacy, limited side effects, availability in a convenient dosage schedule, palatability when provided in suspension, and reasonable cost. When treated with appropriate antimicrobial therapy, a patient should have substantial resolution of signs and symptoms within 72 hours and absence of signs of relapse, recurrence, or suppurative sequelae.

The 2013 AAP/AAPF AOM guidelines for initial management of uncomplicated AOM was updated. The updated guidelines differentiate treatment based on the child's age, unilateral or bilateral AOM, and severity of the child's symptoms. High-dose amoxicillin (80–100 mg/kg per day, with a maximum dose of 3 g) is the recommended first-line treatment in most patients. The selection of high-dose amoxicillin has been made on the basis of the long-term safety of the drug; a first intention to treat penicillin-resistant *S. pneumoniae* since that organism can cause the most morbidity; and the recognition that overdiagnosis of AOM is commonplace, and, as a consequence, emergence of antibiotic-resistant microbes occurs more frequently with broader spectrum antibiotics. However, the guidelines point out that a number of antibiotics are clinically effective. In children who have been treated with amoxicillin in the prior 30 days or who have purulent conjunctivitis or in those children who are more likely to have β -lactamase-producing nontypeable *H. influenzae* or *M. catarrhalis*, therapy should be initiated with high-dose amoxicillin-clavulanate (80–100 mg/kg per day of amoxicillin, with

TABLE 16.6 Daily Dosage Schedule for Antimicrobial Agents With Indications for the Treatment of Acute Otitis Media

Agent	24-Hour Dosage
Amoxicillin	40–80 mg/kg in 2–3 doses
Amoxicillin-clavulanate	40–100 mg/kg in 2 doses
Cefprozil	30 mg/kg in 2 doses
Cefpodoxime	10 mg/kg in 2 doses
Cefaclor	40 mg/kg in 2–3 doses
Cefixime	8 mg/kg in 1 dose
Cefuroxime axetil	30 mg/kg in 2 doses
Loracarbef	30 mg/kg in 2 doses
Ceftriaxone	50 mg/kg in 1 dose (1–3 days)
Ceftibuten	9 mg/kg in 1 dose
Cefdinir	14 mg/kg in 1–2 doses
Erythromycin-sulfisoxazole	50 mg/kg erythromycin, 150 mg/kg sulfisoxazole in 4 doses
Clarithromycin	15 mg in 2 doses
Azithromycin	30 mg/kg in 1 dose (1 day)
	10 mg/kg in 1 dose (3 days)
	10 mg/kg in 1 dose (day 1); 5 mg/kg in 1 dose (days 2–5)
Trimethoprim-sulfamethoxazole	8 mg trimethoprim, 40 mg sulfamethoxazole in 2 doses

6.4 mg/kg per day of clavulanate), a ratio of amoxicillin to clavulanate of 14:1, given in two divided doses, which is less likely to cause diarrhea than other amoxicillin-clavulanate preparations.

Following the introduction and wide use of PCV7 and now PCV13 in the United States, nontypeable *H. influenzae* and *M. catarrhalis* are more common causes of AOM than penicillin-nonsusceptible *S. pneumoniae*. Given the current otopathogen mix and antibiotic resistance, the best choice of antibiotic would be high-dose amoxicillin-clavulanate (90 mg/kg per day divided twice daily). Amoxicillin would not be considered the most effective antibiotic for empiric selection because it has no activity against β -lactamase-producing bacteria, currently far more common than penicillin-resistant *S. pneumoniae*. The addition of clavulanate as a β -lactamase-neutralizing product would provide anticipated efficacy against β -lactamase-producing *H. influenzae* and *M. catarrhalis* while maintaining excellent antimicrobial activity against penicillin-resistant *S. pneumoniae*. There are two disadvantages to amoxicillin-clavulanate: the suspension formulation has a marginal taste that can cause nonadherence to the prescribed regimen, and it causes more loose stools and diarrhea than amoxicillin and many cephalosporin alternatives.

The oral cephalosporins of choice for treatment of AOM, as designated by the AAP, are cefdinir, cefuroxime axetil, and cefpodoxime proxetil. Among these choices in the United States, cefdinir has emerged as the most frequently used, largely because the bitter taste of the other two drugs can be an obstacle for adherence. Cefdinir can be dosed once or divided twice daily (14 mg/kg per day). The duration of treatment with cefdinir can be 5 days with twice-daily dosing or 10 days with once-daily dosing. In a head-to-head comparison of amoxicillin-clavulanate 80 mg/kg per day divided twice daily for 10 days versus cefdinir 14 mg/kg per day divided twice daily for 5 days, amoxicillin-clavulanate demonstrated superior efficacy.²² However, outside the context of a clinical trial, the adherence characteristics favor cefdinir (better taste and less diarrhea).

The taste of cefuroxime and cefpodoxime can be masked with chocolate syrup, but the addition of flavorings at the pharmacy should not be advised since these antibiotics have been shown to precipitate with changes in pH and chemical reactions between the active drug and the flavoring ingredients.

Ceftriaxone by injection (50 mg/kg per dose) is among the preferred antibiotics in the case of initial antibiotic treatment failure in AOM. Ceftriaxone is effective as a single injection against all penicillin-susceptible *S. pneumoniae* and against β -lactamase-producing *H. influenzae* and *M. catarrhalis*. Three doses of ceftriaxone are needed for penicillin-resistant *S. pneumoniae*.⁸³ In light of the long half-life of ceftriaxone, it may be possible to administer the sequential doses spaced every other day or even every third day if weekends or holidays dictate an alternative regimen.

Macrolides, such as erythromycin and azithromycin, have poor efficacy against both *S. pneumoniae* and *H. influenzae*. Clindamycin is also included as a treatment alternative for AOM following failure of other preferred first- and second-line agents. Clindamycin is ineffective against β -lactamase-producing *H. influenzae* and *M. catarrhalis* and only effective against penicillin-susceptible and penicillin-resistant *S. pneumoniae*. Its use might best be limited to cases where a tympanocentesis has been performed and the persisting bacteria and antimicrobial susceptibilities are identified.

Antibiotics not listed in the AAP/AAFP guidelines are omitted because of concerns about poor efficacy, poor adherence, or safety. Therefore, the use of alternatives not included in the guideline should be undertaken after due consideration.

Tympanocentesis as Treatment

Tympanocentesis is a treatment for AOM if performed with the intention of evacuating pus, microbes, and proinflammatory fluid from the middle ear space. Not all tympanocenteses are performed with evacuation of middle ear fluid, and that fact complicates the interpretation of available clinical studies of the therapeutic benefit of the procedure. Tympanocentesis can be performed in an office practice setting without anesthesia or conscious sedation in the hands of a person skilled in the procedure. Instillation of 8% tetracaine into the external canal and placement of an otowick to assure the anesthetic reaches the tympanic membrane are effective to allow the procedure to occur without the child experiencing pain. However, the child must be restrained to avoid head movement during the procedure, and children typically cry when they are restrained. Tympanocentesis is not a frequently performed procedure because most clinicians have not been trained how to do it, and those who have been trained become concerned about its use as a standard of care despite the AAP and U.S. Centers for Disease Control recommendation for selected use in AOM management. Tympanocentesis alone is not as effective as tympanocentesis followed by antibiotics if evacuation of middle ear pus is not achieved.⁶⁵

Using a stringent clinical diagnosis (bulging or full tympanic membrane, cloudy or purulent effusion, and reduced or absent tympanic membrane mobility) followed by tympanocentesis for microbiologic diagnosis of AOM, the effects on recurrent AOM and tympanostomy tube placement in children younger than 3 years of age have been studied. The use of strict diagnostic criteria, tympanocentesis, and empiric antibiotic treatment using evidence-based knowledge of circulating otopathogens and their antimicrobial susceptibility profile reduces the frequency of recurrent AOM and tympanostomy tube surgery.¹¹⁰

Watchful Waiting

In 2004, the AAP/AAFP endorsed a recommendation for watchful waiting as an option for management of AOM in selected cases. The main concept was to allow observation as an option when the diagnosis is uncertain (unlikely in AOM) as long as the child was older than 2 years and reevaluation could occur if the child did not improve in 48 to 72 hours or worsened at any time. The AAP guidelines may have resulted in a reduction of AOM by establishing precise criteria for diagnosis, but a study indicated that there was no evidence that the pattern of prescribing antibiotics for AOM was altered.³⁴ Because of the limitations of the clinical trials that supported the strategy of watchful waiting, investigators in Pittsburgh, Pennsylvania, and Turku, Finland, independently conducted a randomized blinded trial of amoxicillin-clavulanate compared with placebo in children younger than 2 and 3 years, respectively. Amoxicillin-clavulanate showed a significant benefit in the duration of acute signs of illness as compared with placebo.^{63,133} The 2013 AAP/AAFP AOM guidelines removed the “uncertain” diagnosis

and encouraged practitioners to make every effort to use more stringent criteria for the diagnosis of AOM. The guidelines again endorsed the watchful waiting recommendation for children older than 2 years of age with bilateral or unilateral AOM without otorrhea and in children of any age with unilateral AOM without otorrhea and severe symptoms. Again there must be a mechanism in place for prompt reassessment if the child does not improve within 48 to 72 hours or if the child worsens at any time.⁸¹

Pain Management

There can be considerable pain with AOM, especially in the first 24 hours, and pain management for AOM has received more attention with the publication of the AAP's policy statement on the assessment and management of acute pain in infants, children, and adolescents.¹ A child with suspected or confirmed AOM should be given pain treatment regardless of the use of antibiotics. Various treatments of otalgia have been used; however, none has been well studied. Typically pain control is managed with oral analgesics such as acetaminophen or ibuprofen in weight-appropriate doses. The use of otologic analgesic ear drops is also to be considered, although the evidence of efficacy is limited.⁴⁹

Antihistamines and decongestants taken orally or intranasally are not recommended as treatment for AOM or OME because they either have been shown to be nonefficacious or have not been studied at all. They may provide some symptomatic treatment of nasal allergies or nasal congestion.

Duration of Treatment

The optimal duration of antibiotic treatment is generally considered to be 10 days in the United States; however, there is scant evidence for that recommendation. Instead, the 10-day treatment course for AOM was derived from the 10-day treatment course for streptococcal pharyngitis, which is evidence based. Treatment regimens of 1 day, 3 days, 5 days, 7 days, and 10 days are all standard in different countries. The 2013 AAP/AAFP guidelines endorse 10 days of treatment duration as the standard for most AOM but state that shorter treatment regimens may be as effective. A systematic analysis and a meta-analysis have concluded that 5 days' duration of antibiotics is as effective as 10 days of treatment for all children older than age 2 years and only marginally inferior to 10 days for children under the age of 2 years.⁷⁶ A comparison of 5-, 7-, and 10-day treatments of AOM concluded that 5-day treatment was equivalent to 7- and 10-day treatment for all ages unless the child had a perforated tympanic membrane or had been treated for AOM within the preceding month (because recently treated AOM was associated with more frequent causation of AOM by resistant bacteria and with a continued inflamed middle ear mucosa).¹¹¹

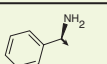

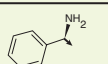

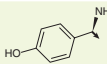

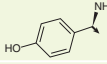

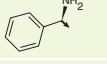

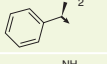

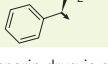

Treatment in the Penicillin-Allergic Child

The use of cephalosporins in penicillin-allergic children has been recently reevaluated. The cephalosporins selected by the AAP took consideration of the likelihood of cross-reaction with penicillin. Second- and third-generation cephalosporins have chemical side chain structures sufficiently distinct from penicillin and amoxicillin that they may be used in penicillin- and amoxicillin-allergic children. The β -lactam ring is not the structure accountable for allergy; it is the side chain. There is some cross-reactivity among cephalosporins based on their shared chemical side chain structure (Tables 16.7 and 16.8).^{4,106,108,109} The possibility of allergy to all penicillins and cephalosporins has never been confirmed as a reality, and statistically the likelihood of such a case is indeed very small.

Management of Otitis Media With Effusion

The presence of middle ear effusion without clinical signs or symptoms of inflammation is defined as OME. The two treatment options recommended for persistent OME are watchful waiting and insertion of tympanostomy tubes. Use of oral systemic steroids is not recommended because the evidence in support of their use was deemed insufficient by a US guideline review panel. When used, oral steroids in a burst similar to the burst used in the management of an acute asthma exacerbation (1 to 2 mg/kg per day in the morning for 5 to 7 days) and subsequent examination to determine if the effusion clears might be considered

TABLE 16.7 Structural Similarities of Cephalosporins to Penicillin Derivatives^a

100% Identical R1 Side Chain		Similar R1 Structural Components	
Cefaclor (second) [ampicillin]		Cefamandole (second)	
Cefadroxil (first) [amoxicillin]		Cefonicid (second)	
Cefatrizine (first) [amoxicillin]			
Cefprozil (second) [amoxicillin]			
Cephalexin (first) [ampicillin]			
Cephaloglycin (first) [ampicillin]			
Loracarbef (second) [ampicillin]			

^aThe generation of the cephalosporin drug is shown in parentheses. The penicillin derivative whose R side chain is 100% identical to the cephalosporin R1 side chain is shown in brackets. These drugs are either known to elicit an allergic reaction in penicillin-allergic patients or, due to their similarity to the penicillin derivative, are suggested to be avoided in patients with known allergies to those penicillins. From Pichichero ME, Zagursky R. Penicillin and cephalosporin allergy. *Ann Allergy Asthma Immunol.* 2014 May;112(5):404–12.

before referral to an ENT specialist for tympanostomy tube insertion. The indication to move from watchful waiting to ENT referral is persisting OME for 6 months in one ear or 3 months in both ears associated with a 30-dB hearing loss in the speech range (see the “Surgical Options” section for further discussion).

Biofilms

OME can become chronic (>3 months in duration). When this occurs, there is ample evidence to suggest that the common otopathogens form a biofilm in the middle ear and on the adenoids. Biofilms involve microbes forming a colony that reduces their process of dividing, slows their metabolism, and allows them to communicate with each other to share survival mechanisms through a process called *quorum sensing*. Biofilm colonies exist in a matrix of DNA and cover themselves with a shield of biomaterial that prevents the penetration of antibiotics and antibodies.⁷ Colonies occasionally shed a few organisms from the colony, and these microbes change their biology and are termed *planktonic*. When biofilms form in chronic OME they consist of the major otopathogens as single species or as polymicrobial colonies consisting of two or even three species of otopathogens.¹¹⁴ Because biofilms do not elicit an immune response, there is little clinical evidence that they exist since there is minimal inflammation in the middle ear when biofilms are present.

Recurrent Acute Otitis Media

The child who returns to the clinician within a month after an initial treatment of AOM with another AOM can be a difficult diagnostic dilemma. In the pre-PCV era, most episodes of true bacteriologic relapse occurred within 2 weeks of the initial diagnosis and were caused by nontypeable *H. influenzae*.⁸² In the PCV7 era following initial treatment with amoxicillin-clavulanate, nontypeable *H. influenzae* caused true bacteriologic-recurrent AOM 77% of the time compared to 23% due to *S. pneumoniae*. A relapse of AOM with the same otopathogen most commonly occurred within 14 days of the original infection, and a new AOM episode was more likely to occur more than 14 days from the original diagnosis.⁷¹

Some children experience enough repeated AOM episodes that they reach a threshold at which they are termed *otitis prone*. The definition of otitis prone has varied among investigators in the field; however, the most frequently used definition currently is three episodes of AOM within 6 months or four episodes within 12 months. Children who experience their first AOM at younger than 6 months, who are male, who attend daycare, and who are exposed to passive cigarette smoke are more likely to experience recurrent AOM.⁴² Children with recurrent AOM are generally treated with broader spectrum antibiotics as additional cases of infection occur. This leads to a concerning cycle of escalation of the antimicrobial resistance of bacteria causing AOM in children with recurrent infections. The 2013 AAP/AAFP guidelines address recurrent AOM for the first time. The use of prophylactic antibiotics has shown no benefit⁸⁰ in the reduction of additional episodes of AOM in children who experience recurrent AOM and has fallen into disfavor in an era of increasing antimicrobial resistance and an evolving understanding of the role of the resident microbiome of the gut and upper airways in maintaining health.⁸¹ Insertion of tympanostomy tubes may be an option and is widely used for both OME and recurrent AOM (see “Surgical Options” for further discussion).

IMMUNOLOGY

Why do some children experience recurrent AOM while others experience infrequent AOM or no AOM at all? Anatomic dysfunction has been identified as a key element to susceptibility to frequent AOM in some children based on observations of those with poor eustachian tube function, such as children with cleft palate and Down syndrome.⁴⁵ However, in recent years the immune response to AOM has come under increased study, and new evidence has emerged to explain susceptibility to an increased frequency of AOM in otitis-prone children.^{69,70,74,126,127,132}

Essentially, some of the children who experience frequent AOM have immune responses to the otopathogens causing AOM that are not as robust as the response of non-otitis-prone children. Their immune response is immature, resembling a neonatal-like immune profile.^{69,70,74,126,127,132} These children have poor innate and adaptive immune responses to AOM infections. The adaptive immune system includes B cells that mature to plasma cells and plasma cells that produce antibodies. T cells help the B cells mature into plasma cells. B and T cells can also become memory cells. In otitis-prone children this adaptive response is deficient. After an AOM, the immune system of the otitis-prone child fails to generate an immune memory response.^{126,127}

The antigen presenting cells (APCs) bridge the innate immune system to the adaptive immune system. APCs are also immature in their responses to the causative otopathogens and are neonatal-like in some children who are otitis prone.¹³²

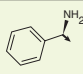

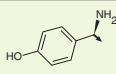

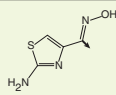

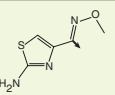

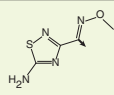

Therefore the otitis-prone child with these deficient immunologic responses remains susceptible to another AOM following antibiotic treatment even by the same otopathogen residing in the nasopharynx that caused a preceding AOM. These immune dysfunctions set the stage for the child to experience recurrent episodes of AOM and become otitis prone.

PREVENTION

Advising Parents

Parents of children who have severe and recurrent otitis media or risk factors for developing middle ear infections should be advised of measures that may reduce the incidence of infection, such as breastfeeding; enrolling children in small, rather than large, group daycare centers; discontinuation of bottle propping; and reducing exposure to tobacco smoke. In addition, data about the risks for developing recurrent otitis media associated with use of a pacifier may be added to the discussion with the parent. Physicians also may advise parents that the seasonal incidence of otitis media suggests that their child's condition is expected to improve in late spring and summer and that aggressive measures of management, including surgery, may be postponed until the course of disease has been determined in the next respiratory season.

^bThis group contains a 4-(aminomethyl)phenol core.

^cThis group contains an (E)-2-aminothiazole-4-carbaldehyde oxime core.

^dThis group contains an (E)-2-aminothiazole-4-carbaldehyde O-methyl oxime core, except for cefixime, which contains an attached formic acid to O-methyl oxime; ceftazidime, which contains an attached propionic acid to O-ethyl oxime; ceftibuten, which contains a but-3-enoic acid moiety in place of the formaldehyde O-methyl oxime moiety; and cefcapene, which contains a but-1-en-1-yl moiety in place of the formaldehyde O-methyl oxime group.

^eThis group contains a 2-methylthiophene core, except for cefoxitin, which also contains a 7-methoxy group on the β -lactam ring.

^fThis group contains an (E)-5-amino-1,2,4-thiadiazole-3-carbaldehyde O-methyl oxime core, except for ceftobiprole, which contains O-methyl oxime replaced with oxime; cefluprenam, which contains O-methyl oxime replaced with O-fluoromethyl oxime; and ceftaroline fosamil, which contains the (E)-5-amino group replaced with an (E)-5-phosphonoamino group and the O-methyl oxime replaced with an O-ethyl oxime group.

^gThis group contains a 1-methyl-1H-tetrazole core.

Vaccinations to Prevent Acute Otitis Media

Pneumococcal Vaccines

The 2013 AAP/AAFP AOM guidelines recommend vaccination with the pneumococcal vaccine to help with the prevention of AOM. In developed countries, virtually all children are vaccinated with PCV13. The predecessor vaccine PCV7 was shown to be effective in preventing AOM due to the seven serotypes contained in the vaccine. Escape serotypes replaced the seven serotypes in PCV7 over time. Based on the emergence of escape serotypes the newer PCV13 was developed to include the original seven serotypes and the six additional serotypes that had emerged as fairly common.

The 10-valent pneumococcal polysaccharide vaccine (PCV10) conjugated with an outer membrane protein of nontypeable *H. influenzae* also is effective against AOM caused by *S. pneumoniae* strains expressing the capsular serotypes included in the vaccine. In the pivotal licensure trial for PCV10, a reduction of 35% of episodes caused by nontypeable *H. influenzae* was observed. The vaccine is now available in Europe, Canada, South America, and other regions but not in the United States.

The 23-valent pneumococcal polysaccharide vaccine currently available produces an antibody response in children 2 years of age or older. The polysaccharide vaccine is effective in preventing type-specific pneumococcal otitis media if an adequate immune response occurred, but the number of types producing an adequate response is limited. Administration of the polysaccharide vaccine in older children may

provide protection against types not included in PCV13 and has been recommended by the AAP and the Advisory Committee on Immunization Practices of the Surgeon General for high-risk children aged 2 years and older who have received PCV13. Table 16.9 shows the currently available pneumococcal vaccines worldwide. Repeated boosting with polysaccharide vaccines has come under scrutiny since a process called “terminal B cell differentiation” may occur whereby B cells respond by producing less antibody and then die before developing into B memory cells.

Influenza Virus Vaccines

Inactivated influenza virus vaccines result in a reduction in cases of influenza-associated AOM in children.⁶² A similar reduction in episodes of influenza-associated AOM was reported in children after administration of a live, attenuated cold-adapted intranasal vaccine.¹⁰ Annual administration of influenza virus vaccines should be part of the strategy for reducing the incidence of AOM for children with recurrent and severe disease, as recommended by the 2013 AAP/AAFP guidelines.⁸¹

Respiratory Syncytial Virus Vaccine

Respiratory syncytial virus (RSV) is more frequently found in children with AOM than any other virus.¹⁰³ The risk of development of AOM after viral URI has been well studied. A total of 57% of children with RSV infection develop AOM as compared to 35% for influenza A virus;

other viruses had lower rates of AOM.¹²² An earlier study showed a somewhat lower risk of AOM (33%) following RSV infection, although it was still the most common virus associated with AOM.⁶¹ Not all respiratory viruses may be equal in their predisposition toward AOM. An effective vaccine against RSV is likely to have the highest impact against the occurrence of AOM following URI.

COMPLICATIONS AND SEQUELAE

Otitis media, with and without its associated hearing loss, can affect a child's development, behavior, and quality of life. Intracranial suppurative complications of otitis media, including meningitis, brain abscess, and lateral sinus thrombosis, are uncommon occurrences today in developed countries but are still prevalent in developing nations. Intratemporal complications that occur within the aural cavity and adjacent structures of the temporal bone are seen more commonly. They include acute and chronic perforation of the tympanic membrane, chronic suppurative otitis media, mastoiditis, cholesteatoma and retraction pocket, adhesive otitis media, tympanosclerosis, and ossicular discontinuity and fixation. The most frequent complication is hearing loss that occurs whenever the middle ear cavity is filled with fluid, when a perforation of the eardrum occurs, and, less commonly, when the ossicles are impaired.

Hearing Loss

Fluctuating or persisting hearing loss is present in most children who have middle ear effusion; impairment of hearing is the most prevalent complication of otitis media with effusion. Audiograms of children with middle ear effusion usually reveal a mild to moderate conductive loss of 15 to 40 dB. With such deficits, the softer speech sounds and

voiceless consonants may be missed. The hearing loss is not influenced by the quality of fluid in the middle ear; ears with thin fluids are impaired to the same degree as are ears with fluids of glue-like consistency. The hearing impairment usually is reversed with resolution of the effusion. Uncommonly permanent conductive hearing loss occurs because of irreversible changes from the inflammatory reaction in the middle ear space, resulting in adhesive otitis media or ossicular discontinuity. High negative pressure in the middle ear or atelectasis in the absence of effusion also may cause conductive loss.

Sensorineural hearing loss after a case of AOM is rare but may occur as a result of increased tension and stiffness of the round window membrane and is reversible. A permanent sensorineural loss may occur due to spread of infection or products of inflammation through the round window membrane.

Mastoiditis

Mastoiditis continues to be an important complication of AOM in developed countries, although at a low rate of about 1% of cases. Untreated otitis media may lead to persistent perforation of the tympanic membrane, dysarticulation of ossicles, and mastoiditis.

At birth, the mastoid consists of a single cell, the antrum, connected to the middle ear by a small channel, the aditus ad antrum. Pneumatization of the mastoid bone occurs soon after birth and usually is extensive by the time the child reaches 2 years of age. It is likely that whenever AOM occurs, some degree of mastoiditis is present. With healing of the middle ear infection, healing of the mastoid also occurs. In a few cases, mastoid disease progresses with hyperemia and edema of the mucosal lining of the pneumatized cells, accumulation of serous and then purulent exudates in the cells, demineralization of the cellular walls and necrosis of bone, and formation of abscess cavities caused by coalescence of adjacent cells after destruction of the cell walls. Pus may escape into contiguous areas, including the posterior cranial fossa, middle cranial fossa, sigmoid and lateral sinuses, canal of the facial nerve, semicircular canals, and petrous tip of the temporal bone.

Signs of acute mastoiditis with periostitis include fever, otalgia, postauricular erythema, tenderness, and slight swelling. The pinna may be displaced inferiorly and anteriorly.

Initial management of acute mastoiditis includes administration of parenteral antibiotics and myringotomy to provide drainage of the middle ear and mastoid contents. Surgical drainage of the mastoid should be performed if the symptoms of the acute infection, including fever and otalgia, persist. If the infection progresses, causing destruction of the bony trabeculae, and a mastoid empyema results, mastoidectomy should be performed to prevent spread of the infection to adjacent structures.

Petrositis

Petrositis occurs when suppurative infection extends from the middle ear and mastoid into the petrous portion of the temporal bone. Signs of petrositis include pain behind the eye, deep ear pain, persistent ear discharge, and sixth-nerve palsy. The triad of pain behind the eye, aural discharge, and sixth-nerve palsy is termed *Gradenigo syndrome*. Management is similar to that described earlier for mastoiditis.

Labyrinthitis

Spread of AOM into the cochlear and vestibular apparatus through the round (less commonly, the oval) window results in inflammation of the labyrinth. The signs of labyrinthitis include sudden, progressive, or fluctuating sensorineural hearing loss or vertigo in association with otitis media or mastoiditis. Signs of suppurative labyrinthitis (in the absence of meningitis) warrant performing aggressive otologic surgery and administering parenteral antimicrobial therapy.

Meningitis

Meningitis may be associated with middle ear infections in three circumstances:

1. *Direct invasion:* A suppurative focus in the middle ear or mastoid spreads through the dura, extends to the pia-arachnoid, and causes generalized meningitis.

2. *Inflammation in an adjacent area:* The meninges may become inflamed if there is suppuration in an adjacent area, such as the mastoid air cells.
3. *Concurrent infection:* Otitis media arises by spread of bacteria from the upper respiratory tract, and meningitis concurrently invades the blood from the upper respiratory focus.

Children with cochlear implants are at risk for development of meningitis. Imaging of the temporal bone and inner ear should be performed before cochlear implantation to identify inner ear malformations or cerebrospinal fluid fistulas or ossification of the cochlea that might increase risk of bacterial meningitis after surgery. Although the implant has been implicated in the subsequent development of meningitis, some children likely had an underlying congenital inner or middle ear malformation that provided a pathway for the bacterium to enter the cerebrospinal fluid.

Facial Paralysis

Facial paralysis may occur as a sequela of AOM because of exposure of the facial nerve in the middle ear cleft caused by a bony dehiscence. The palsy usually is unilateral. The paralysis frequently resolves with medical therapy for AOM, but a tympanocentesis (diagnosis of organism) and myringotomy for drainage may be required if the paralysis persists, and, on rare occasions, a facial nerve decompression may be necessary.

Other Suppurative Complications

The middle ear and mastoid air cells are adjacent to the dura of the posterior and middle cranial fossa, the sigmoid venous sinus of the brain, and the inner ear. Suppuration in the middle ear or mastoid may spread to these structures, producing suppurative complications such as meningitis, extradural abscess, subdural empyema, focal encephalitis, brain abscess, and lateral sinus thrombosis. Intracranial complications should be suspected when a child with acute or chronic otitis media develops persistent and severe headache, severe otalgia, and change in affect or level of responsiveness. Conversely, children with diagnosed intracranial infection, such as meningitis, should have middle ear or mastoid disease assessed as the origin of the central nervous system disease.

Intracranial extension of infection from the middle ear into the intracranial area may occur because of any of the following:

1. Progressive thrombophlebitis, permitting infection to spread through the intact bone
2. Erosion of the bony walls of the middle ear or mastoid
3. Extension along preformed pathways such as the round window, dehiscent sutures, skull fractures, and congenital or surgically acquired bony dehiscences

Vestibular Dysfunction

Middle ear effusion can cause disequilibrium and even vertigo, apparently secondary to the inflammatory process crossing the round window membrane or pressure on the oval or round windows. Tympanostomy tube placement can relieve the symptoms as long as labyrinthitis (spread of infection into the balance system of the inner ear) is not the cause.

Effects of Otitis Media on Development of the Child

Children with severe or recurrent otitis media have prolonged time spent with middle ear effusion. Hearing impairment accompanies the effusion in most children. Because language acquisition is dynamic during infancy, any problems in receiving or interpreting sound signals might have a temporary effect on development of speech and language.

Although many studies have been done and are reviewed in the clinical practice guideline “Otitis Media with Effusion in Young Children” published by the Agency for Health Care Policy and Research of the US Department of Health and Human Services, the limitations of design of many of the studies and inconsistencies of the results limit the ability to make conclusions about the effect of otitis media on development. The interested reader should consult the guideline for a valuable review and extensive bibliography. A study by Paradise and colleagues¹⁰² indicates that early placement of ventilating tubes in children with prolonged time spent with middle ear fluid did not measurably improve developmental outcomes at age 3 years.

Perforation of the Tympanic Membrane and Chronic Suppurative Otitis Media

Acute perforation (not caused by trauma) usually is secondary to AOM. The perforation occurs because of pressure of the expanding middle ear contents on the membrane, resulting in local ischemia and tissue damage, usually in the central portion of the membrane. With rupture, the pus is discharged into the external ear canal, with instant relief of pain from the acute infection. Because the membrane is highly vascular, the perforation may seal quickly and not be evident within hours. If the mucous membrane of the middle ear remains inflamed, fluid may reaccumulate behind the resealed tympanic membrane.

Chronic perforation may occur after an acute episode, spontaneous extrusion, or removal of a tympanostomy tube. If squamous epithelium grows at the edges of the perforation, healing may be prevented, and the perforation persists. The term *chronic suppurative otitis media* is limited to a stage of ear disease in which chronic inflammation of the middle ear and mastoid occurs and in which a nonintact tympanic membrane (caused by perforation or tympanostomy tube) and otorrhea are present. Mastoiditis usually is present, and a cholesteatoma may have formed.¹⁸ Surgical repair of a chronic perforated tympanic membrane is presented later, in the section “Surgical Options”.

Cholesteatoma

A cholesteatoma usually is a cystic structure lined by squamous epithelium resting on a fibrous strand. The contents of the cyst are the products of desquamation, keratinization, and pus formation. A cholesteatoma may invade, causing local bone erosion and destruction of the ossicles. Aural cholesteatomas can be classified as congenital or acquired.

A congenital cholesteatoma is a congenital collection of epithelial tissue and appears as a white cystlike structure within the middle ear or temporal bone. Acquired cholesteatoma may be secondary to implantation of epithelial tissue or may be a sequela of otitis media, a retraction pocket, or both. Implantation cholesteatoma may develop either from epithelium that has migrated through a perforation of the tympanic membrane or from intraaural epithelium remaining after middle ear or mastoid surgery. A recent histologic study concluded that cholesteatoma can result from stimulated migration of squamous epithelium from the tympanic membrane. Initial management includes initiation of parenteral antibiotics and tympanocentesis (diagnosis of causative organism). Management of cholesteatoma is surgical removal of the entire cyst. Antimicrobial therapy may be necessary if secondary infection is present (see “Surgical Options”).

Adhesive Otitis Media

Adhesive otitis media is a result of healing after chronic inflammation of the middle ear and mastoid. Fibrous tissue proliferates in the mucosal lining and may impair movement of the ossicles and result in conductive hearing loss. Adhesive changes may bind the eardrum to the ossicles and surrounding middle ear structures and cause resorption of the ossicles.

Tympanosclerosis and Tympanic Atrophy

Tympanosclerosis, or scarring of the tympanic membrane, is a common sequela following insertion of tympanostomy tubes. White plaques are present in the tympanic membrane and represent calcium deposits in the submucosal layers after blood resorption following the surgical incision of the tympanic membrane.

Tympanic atrophy, or thinning of the tympanic membrane, is also a common sequela following tympanostomy tubes. The thinned area often appears as a round area where the tube was previously inserted and subsequently extruded spontaneously or removed surgically. Tympanic atrophy is associated with mild but measurable hearing loss, depending on the total area of atrophy of the eardrum. Repeated insertions of tympanostomy tubes result in larger areas of tympanosclerosis and atrophy, with the potential for greater measurable hearing loss.

SURGICAL OPTIONS

When nonsurgical methods of prevention fail to prevent recurrent otitis media, surgery is a reasonable option.

Myringotomy and Tympanocentesis

Myringotomy is an incision in the anterior lower quadrant of the tympanic membrane for therapeutic drainage. Tympanocentesis, needle aspiration of middle ear effusion, is used primarily for establishing the presence or absence of an effusion and for microbiologic study. Because cultures of the upper respiratory tract are of limited value in providing specific microbiologic diagnosis of otitis media, only materials obtained by aspiration of the middle ear abscess can be considered a true reflection of the etiology of AOM.⁴⁴ Tympanocentesis, with or without myringotomy, should be considered in patients who at onset appear toxic or are seriously ill, in patients who are toxic after initiation of antimicrobial therapy, in the presence of suppurative complications (including mastoiditis and meningitis), and in immunologically deficient patients in whom an unusual organism may be present.

Myringotomy, Tympanostomy Tubes, and Adenoidectomy

After circumcision, myringotomy with tympanostomy tube insertion (M&T) is the most common surgical procedure performed in children that requires general anesthesia; in the United States, about 2 million tubes are inserted annually through the eardrums of probably more than 1 million individuals in this age group. Currently we now have the results of randomized controlled trials (RCTs) to arrive at criteria for tube insertion and, importantly, official guidelines for indications are now available. A shared decision-making (SDM) approach between the clinician and the patient/family to decide to operate is now preferred. A relatively new lay community, Society for Middle-Ear Disease (SMED) and its website (www.societyformiddleearisease.org), makes available up-to-date information for the professional and caregivers related to myringotomy and tube surgery for this common malady.

Importance of Official Guidelines for Management of Middle Ear Disease

The dissemination of official guidelines on the diagnosis and management of otitis media is an important mission of SMED. One of the leading aims of the society is not only to disseminate these guidelines to health care professionals around the world but also to help lay individuals understand the issues. Most of these guidelines were developed by experts in the field who rely on outcomes of clinical trials that have complied with the scientific rigor needed to answer clinically important questions (evidence-based medicine). Unfortunately, some recent reports have revealed that noncompliance with these guidelines by physicians remains a problem.³⁰

Official guidelines on the diagnosis and management of otitis media from several countries are presented on the SMED website. Most were written in language best understood by medical professionals and not lay individuals, but some use language directed at parents and other lay caregivers. Thus another important mission of SMED is to empower patients and their families when discussing management (such as M&T with or without adenoidectomy) with their primary care physician and specialist (otolaryngologist). SMED encourages patients and families to be proactive in the decision-making process when faced with options to treat or not treat and with decisions on which treatments are safe and effective. SDM is preferred over the paternalistic approach once common among many clinicians. These discussions should be in terms that the average caregiver fully understands. Dissemination of these guidelines to health care professionals as well as to patients and their caregivers will create more informed and better health care for middle ear disease in the future.

Current guidelines for otitis media from those countries that have them can be found on the SMED website under the heading Guidelines (www.societyformiddleearisease.org).

Randomized Controlled Trials

Otitis Media With Effusion

In the past, several studies addressed the efficacy of M&T for treatment of chronic otitis media with effusion, currently the most common indication, but all had problems in design and methodology. There were, however, four relatively recent well-designed RCTs.

Gates and colleagues⁵¹ evaluated 578 San Antonio, Texas, children in a trial that randomly assigned children aged 4 to 8 years who had

chronic effusion that was unresponsive to antimicrobial therapy into one of four random arms: (1) myringotomy without tube placement, (2) M&T, (3) adenoidectomy and myringotomy, and (4) adenoidectomy and M&T. The investigators concluded that adenoidectomy and myringotomy were superior to M&T alone and, to some degree, more so than adenoidectomy and M&T. Even though they did not recommend the addition of tubes due to the associated otorrhea, after discussion with parents (i.e., SDM), We recommend both in children in this age group who are affected severely by chronic otitis media with effusion. This RCT did not include a control group of no surgery, but all three of the other treatments did statistically better than myringotomy only and were associated with too many procedures. Thus myringotomy alone is not recommended.

Mandel et al. conducted two trials that addressed M&T for this disease. The first was reported in 1989 by Mandel and coworkers⁸⁷ and was an RCT involving 109 Pittsburgh children who had chronic otitis media with effusion that had been unresponsive to antimicrobial therapy. The study randomly assigned subjects to receive (1) myringotomy, (2) myringotomy and tympanostomy tube, or (3) no surgery (control). During this 3-year trial, subjects were evaluated monthly and whenever an ear, nose, and throat illness supervened. Patients who had tympanostomy tubes inserted had less middle ear disease and better hearing than did either children who had only myringotomy or those subjects in the control group. In addition, one-half of the subjects in the myringotomy group had to have tympanostomy tubes inserted during the first year of the trial because of an excessive number of myringotomies and development of "significant" hearing loss; none of these subjects had this degree of hearing loss when they entered the trial. Myringotomy (without tube) provided no major advantage over no surgery (i.e., control) regarding percentage of time with middle ear effusion, number of bouts of AOM, and number of subsequent surgical procedures. It was concluded that myringotomy and tympanostomy tube placement provided more effusion-free time and better hearing than either myringotomy without tube insertion or no surgery, but some patients who received tubes did develop otorrhea, and perforation was a problem in one of the children. Because interpretation of this trial was difficult because of the complexities of the design, the protocol was revised and a second clinical trial was conducted.

In a second trial, reported in 1992, Mandel and colleagues⁸⁸ randomized 111 children into the same three groups as in the first study: (1) myringotomy, (2) myringotomy and tympanostomy tube insertion, and (3) no surgery (control). As in the first trial, subjects were reexamined at least every month for 3 years. Outcomes observed in this trial were similar to those reported in the first study. Again, subjects in the myringotomy and tube group had less time with middle ear effusion and better hearing than either those children who had only a myringotomy performed or the group that had no surgery.

In an RCT, Casselbrant and colleagues,²⁹ compared the efficacy of M&T, adenoidectomy with M&T, and adenoidectomy with myringotomy (without tubes) as the first operative procedure in reducing chronic otitis media with effusion in 2- and 3-year-old children. The investigators concluded that adenoidectomy with or without M&T provided no advantage in this age group.

On the basis of these RCTs, it is recommended that M&T be the first surgical procedure performed, as opposed to myringotomy only or adenoidectomy with M&T for children who have chronic otitis media with effusion of 3 months or longer. Even though Gates and colleagues⁵¹ recommended an adenoidectomy and myringotomy (without tympanostomy tube insertion) as the initial surgical procedure, it is recommended to reserve adenoidectomy for those children who require another surgical procedure if otitis media recurs after extrusion of the initial tube. This recommendation is made since the study by Gates and colleagues showed that adenoidectomy in their population was only a little better than myringotomy and tympanostomy tube and since in the two Mandel trials approximately 50% of the subjects required only one M&T. The RCT conducted by Casselbrant and colleagues²⁹ failed to show an advantage of adenoidectomy with or without M&T as the first surgical procedure. However, if the child has significant nasal obstruction caused by obstructive adenoids, especially causing obstructive sleep apnea, adenoidectomy and myringotomy (with or without

tympanostomy tube insertion) as an initial procedure is a reasonable option; this decision should be shared between the clinician and family (i.e., SDM).

Guidelines: Myringotomy, M&T, and Adenoidectomy for Chronic Otitis Media With Effusion

In 1994, Stool et al.¹³¹ prepared the first clinical practice guideline for otitis media with effusion in young children. That guideline is now outdated. This was followed by a guideline jointly published in 2004 by the American Academy of Otolaryngology–Head and Neck Surgery, the AAP, and the AAFP.² That committee recommended that tympanostomy tube insertion be the preferred initial procedure when a child becomes a surgical candidate and that adenoidectomy not be performed unless another indication is present, such as nasal obstruction or chronic/recurrent acute adenoiditis. Repeat surgery should consist of adenoidectomy plus myringotomy, with or without tympanostomy tube insertion. We are in agreement with this indication but with the option of adenoidectomy for repeat surgery.

More recently, in 2013, the American Academy of Otolaryngology–Head and Neck Surgery published a Clinical Practice Guideline for tympanostomy tubes in children.¹²⁰ This committee recommended tympanostomy tube insertion in at-risk children (e.g., speech, language, or learning problems) with unilateral or bilateral otitis media with effusion that is unlikely to resolve quickly and persists for 3 months or longer.

The latest committee developing guidelines for otitis media with effusion has been convened (2015) by the American Academy of Otolaryngology–Head and Neck Surgery. Following its deliberations and the published report, we will see greater clarification for indications for tubes for this disease entity. (The guideline will be available on the SMED website.)

Recurrent Acute Otitis Media

RCTs have tested the efficacy of tympanostomy tube insertion for prevention of recurrent acute otitis media. Gebhart⁵² in Columbus, Ohio, evaluated otitis-prone infants, of whom 50% had tubes inserted and 50% had no surgery. Efficacy was demonstrated, but infants with middle ear effusion were also enrolled and follow-up was limited to 6 months.

Gonzalez and coworkers⁵⁴ conducted an RCT in the U.S. Army that enrolled 65 otitis-prone infants into a trial that randomly assigned subjects into three groups: (1) sulfisoxazole prophylaxis, (2) myringotomy and tympanostomy tubes, and (3) placebo. Similar to the Gebhart trial, infants entered with and without middle ear effusion, were not stratified, and were observed for only 6 months. Infants in the tympanostomy group did significantly better if they had middle ear effusion at entry, but the attack rate of acute otitis media was not reduced in those subjects who were effusion free at the time of random assignment.

Casselbrant and colleagues²⁸ randomly assigned 264 Pittsburgh children aged 7 to 35 months to one of three groups: (1) amoxicillin prophylaxis (20 mg/kg per day in one dose at bedtime), (2) myringotomy and tympanostomy tube insertion, and (3) placebo. Unlike the two previously reported trials, only patients who had no middle ear effusion were randomized. The children were observed monthly and whenever an ear, nose, and throat illness supervened over the course of 2 years. The average rate of new bouts of AOM was significantly reduced in those subjects who were in the amoxicillin prophylaxis group compared with the tube or placebo group. There was no significant difference between the tympanostomy tube and placebo groups for this outcome measure. Postoperative otorrhea through a tympanostomy tube was an episode of AOM, which occurred at about the same rate as the number of episodes of AOM in the placebo group. However, the bouts of otorrhea were usually asymptomatic and less troublesome than when acute middle ear infection developed in the placebo and amoxicillin prophylaxis groups. When the average of time with otitis media of any type (i.e., acute otitis media, otorrhea, or otitis media with effusion) was evaluated, the tube group had only 6.6% compared to 10% for the amoxicillin group and 15% for subjects who received placebo; tubes had significantly less otitis media of any type than the prophylaxis and placebo groups ($P < .001$). The amoxicillin group had adverse side effects in 7%, primarily urticaria and vaginitis, and 3.9% of the tympanostomy tube group

developed persistent perforation of the tympanic membrane; all of these eventually healed spontaneously. Since relatively long-term antimicrobial prophylaxis is related to the development of resistant bacteria, this question was addressed in the trial, but there were no consistent differences in percentages of β -lactamase-positive *H. influenzae* or *M. catarrhalis* found in serial nasopharyngeal cultures between those who received amoxicillin prophylaxis and those who were in the placebo group. During the 2-year trial, 70% of the subjects who were randomly assigned to the tube group required only one procedure, whereas 26% needed a second set of tubes inserted; only one child (1%) had to have three sets of tubes.

We recommended that amoxicillin prophylaxis be the first method used to prevent recurrent episodes in infants and young children, the age group included in the trial. If this failed, tympanostomy tube placement was the next option. We also recommended that children prescribed prophylaxis be reevaluated periodically even if they are symptom free since asymptomatic middle ear effusion may develop. That recommendation was made before awareness that long-term, low-dose antibiotics, especially amoxicillin, are associated with the emergence of antibiotic-resistant pathogens (e.g., *S. pneumoniae*). Thus antibiotic prophylaxis should be an option presented on an individualized basis, such as for children who are anesthetic risks or whose parents choose to withhold surgery.

More recently, Whittemore,¹⁴⁰ in reviewing the literature for tubes in preventing recurrent acute otitis media, cited our RCT as the only acceptable trial and concluded that the “level of evidence favoring (tube) placement is 1b given there is an individual, randomized, controlled trial.” The researchers then published a letter to the editor²⁷ to clarify certain aspects of our trial since there had been some confusion related to its outcomes; also we wanted to provide our more current recommendations because that report was more than 20 years old. We have addressed this clarification and our recommendations earlier.

To assess the efficacy of adenoidectomy, Paradise et al.¹⁰¹ conducted an RCT in children who had received an M&T in the past and again developed middle ear disease. The team concluded that adenoidectomy was warranted for children who develop recurrent otitis media after extrusion of the previously inserted tubes.

In a follow-up to that trial, Paradise and coinvestigators¹⁰⁰ tested the efficacy of adenoidectomy and adenotonsillectomy for recurrent acute otitis media in children who did not have an M&T in the past and concluded that neither operation was indicated as the first surgical procedure.

Guidelines: Myringotomy and Tympanostomy Tube Placement for Recurrent Acute Otitis Media

The AAP’s 2013 clinical practice guideline on the diagnosis and management of acute otitis media includes this key action statement: Clinicians may offer tympanostomy tubes for recurrent acute otitis media (three episodes in 6 months or four episodes in 12 months, with one episode in the preceding 6 months).⁸⁴ The American Academy of Otolaryngology–Head and Neck Surgery (2013) in their clinical practice guideline on tympanostomy tubes in children included an action statement profile stating that clinicians should offer bilateral tympanostomy tube insertion to children with recurrent acute otitis media who have unilateral or bilateral middle ear effusion at the time of assessment for tube candidacy.¹²⁰ The committee cited the Gebhart⁵² and Gonzalez et al.⁵⁴ studies to support this conclusion. Troubling is the action statement profile that “Clinicians should not perform tympanostomy tube insertion in children with recurrent acute otitis media who *do not* have MEE [middle ear effusion] in either ear at the time of assessment for tube candidacy.” In the Casselbrant et al.²⁸ trial discussed earlier subjects were entered without middle ear disease because we believed the trials by Gebhart⁵² and Gonzales et al.⁵⁴ were confounded by the inclusion of such children, and we wanted to determine the efficacy of tubes in children who present with recurrent acute otitis media who met our criteria but had no middle ear fluid at the time of the initial examination. We believe we showed efficacy in our trial given our election to include any acute infection whether the tympanic membrane was intact or not. We considered post-tube otorrhea to be not the same as acute disease when the eardrum was intact.

Tympanostomy Tube Placement and Physiologic Functions of the Eustachian Tube

As presented earlier, there are now RCT results showing that M&T can be beneficial in selected infants and children since middle ear disease is reduced and hearing is restored, although there are known complications and sequelae associated with the surgery. The rationale for the procedure may be found in certain physiologic and pathophysiologic aspects of the nasopharynx, the eustachian tube, middle ear, and mastoid gas cell system that are related to the pathogenesis of otitis media. The eustachian tube has three important physiologic functions in relation to the middle ear: (1) *pressure regulation* of the middle ear, (2) *clearance* of secretions down the eustachian tube, and (3) *protection* of the middle ear from the entry of unwanted nasopharyngeal secretions. A functioning tympanostomy tube maintains ambient pressure within the middle ear and mastoid and provides adequate drainage both down the eustachian tube and through the tympanostomy tube. Two physiologic functions of the eustachian tube are fulfilled by the tympanostomy tube. But the protective function of the eustachian tube is impaired by tympanostomy tube insertion since a patent tympanostomy tube results in an opening in the tympanic membrane, and the physiologic middle ear gas cushion is not present if the tympanic membrane is not intact. Therefore reflux of nasopharyngeal secretions into the middle ear can occur when a tympanostomy tube eliminates the middle ear gas cushion, a situation that can result in otitis media and otorrhea. The tube can result in organisms from the external canal entering the middle ear to cause tube otorrhea. The 2013 guidelines from the American Academy of Otolaryngology–Head and Neck Surgery¹²⁰ state that tube-associated otorrhea should be treated with topical antibiotic drops and not oral antimicrobial agents for children who have uncomplicated acute tube otorrhea. The ideal eustachian tube prosthesis would be a transtympanic tube that fulfills all three of the important physiologic functions of the eustachian tube: pressure regulation, drainage, and protection¹⁹ (see the SMED website, www.societyformiddleear disease.org).

Other Indications for Placement of Tympanostomy Tubes

Although not supported by clinical trials, other indications for tympanostomy tube placement are:

1. Recurrent otitis media with effusion in which each episode does not become chronic but the cumulative duration is excessive, such as six episodes in the previous 12 months
2. Eustachian tube dysfunction that is chronic or recurrent and unresponsive to medical management; atelectasis of the middle ear that is chronic (with or without retraction pocket)
3. Suppurative complications (e.g., facial paralysis, mastoiditis)
4. Time of tympanoplasty when eustachian tube dysfunction is chronic
5. Prevention of otic barotrauma during hypobaric chamber treatment

Acceptable clinical trials for these relatively uncommon indications are either not feasible due to the limited number of patients, or there are ethical concerns, such as when suppurative complications occur.

The rationale for tubes for middle ear infection that is persistent or when suppurative complications are present is similar to incision and drainage of an abscess in other parts of the body. A tympanostomy tube is excellent for desired drainage that is either short or long term.

When Should Tympanostomy Tubes Be Removed?

In general, once tubes are inserted they should be permitted to extrude spontaneously into the external auditory canal and not be removed too early. The rationale for such management is based on experience rather than on any RCT. In children with tympanostomy tubes in place, eustachian tube function does not change significantly, even after several months. There are differences in the life of tympanostomy tubes depending on the type: some have a short duration, whereas for others the tubes may remain in place for years, such as “permanent” long-term tubes.

Nevertheless there are indications to remove tubes in selected children. Tympanostomy tubes may be removed when still in the eardrum by an otolaryngologist as an office procedure with the aid of an operating microscope and without either local or general anesthesia, especially when the tube is partially extruded or when there is chronic infection

involving the tympanic membrane. In young children, however, tympanostomy tubes are frequently removed by the otolaryngologist under general anesthesia in the operating room since the procedure can be painful, and the rim of the perforation can be denuded of epithelium and the defect closed (i.e., “paper patch” myringoplasty). Moon et al.⁹⁴ recommended tube removal in asymptomatic children when tubes are retained for more than 18 months since spontaneous extrusion seldom occurs after 18 months; removal prior to 12 months resulted in an increased possibility of recurrence, and removal after 15 months showed an increase in complications, such as a perforation of the tympanic membrane.

Removal of tympanostomy tubes depends on several factors, including:

1. Age of the child
2. Duration of time the tube has remained in place
3. Unilateral versus bilateral tubes
4. Status of the contralateral ear when that tympanic membrane is intact
5. Eustachian tube function
6. Presence or absence of recurrent or chronic otorrhea
7. Season of the year
8. Patency of the tube

Complications and Sequelae

As discussed earlier, post-tympanostomy tube otorrhea is a frequent complication but usually effectively treated with ototopical antibiotic drops; a recent study found that antibiotic-glucocorticoid ear drops were more efficacious and cost-effective than oral antibiotics.¹³⁶ However, there are other complications and sequelae. Scarring of the tympanic membrane (myringosclerosis) is present in up to half of patients after surgery and can be either localized or even result in diffuse atrophy of the eardrum, with or without a retraction pocket; tympanosclerosis is rarely present in the middle ear and ossicular chain, and thus hearing loss is rare. Atelectasis can occur in which the tympanic membrane becomes flaccid and, in the presence of middle ear negative pressures, can adhere to the medial wall of the middle ear and ossicles. Although many have questioned the presence of long-term hearing loss following tube insertion, the 25-year follow-up study after tube placement by Khodaverdi and colleagues⁷⁵ concluded that M&T had no impact on long-term hearing levels; that study also found that hearing loss associated with pathology (e.g., atrophy and myringosclerosis) was more common following tube placement than in non-tubed ears, but the levels were too small to have an impact.

Post-tympanostomy tube perforation of the eardrum can occur following spontaneous extrusion or removal, with the rate varying with the type of tube, number of insertions, and life of the tube; perforation occurs more frequently after “permanent” tubes are extruded or removed. Postoperative tympanostomy tube obstruction is common. A recent study reported a rate of 10.6% and that serous middle ear effusion at the time of surgery and an increased time to the postoperative visit were statistically significant indicators for occlusion.³⁵ When a tube is obstructed, usually with dried mucus, it may be opened with thin-viscosity ototopical drops. If this is unsuccessful, in older teenagers and adults, it can be opened using a thin wire under the visualization of an operating microscope; in infants, and with caregiver acceptance, it can also be opened using a thin wire procedure but with the infant restrained. When all else fails, the tube can be replaced. Very rarely an acquired cholesteatoma occurs at the site of placement, but, when identified early at postoperative follow-up visits, it can be removed with minor surgery. In general, complications and sequelae associated with tympanostomy tube placement are either transient (e.g., otorrhea) or cosmetic, such as myringosclerosis.⁷³

A description of how M&T is performed is available on the SMED website (www.societyformiddleear disease.org).²⁰

Other Surgical Procedures

Of the other surgical operations for otitis media and its complications, procedures to repair the perforated eardrum are an option. Myringoplasty is an operation that closes the perforated tympanic membrane with a graft or other material, but the middle ear is not entered. Tympanoplasty

is also a procedure to repair the tympanic membrane with graft, but the middle ear is opened to inspect the ossicles and the remainder of the middle ear. If ossicles are absent or otherwise abnormal, they can be corrected with an ossiculoplasty. Mastoidectomy for chronic suppurative otitis media and for cholesteatoma is not as common as the procedures described earlier but is still an important component of the otolaryngologist's role in providing surgical care for infants and children who have complications of otitis media.

Descriptions of how these operative procedures are performed are available on the SMED website (www.societyformiddleeardisease.org).²⁰

Mastoiditis

17

James D. Cherry • Andrew M. Vahabzadeh-Hagh • Nina L. Shapiro

Mastoiditis, a suppurative infection of the mastoid air cells, is a potential complication of all cases of otitis media caused by the continuity of the mucoperiosteal lining of the mastoid with that of the middle ear.¹⁴ The spectrum of disease in mastoiditis ranges from asymptomatic cases with apparent spontaneous resolution to progressive disease with life-threatening complications.¹⁴ Since the advent of antibiotic therapy, mastoiditis is seen much less frequently, but the complications remain similar.^{25,29,31,116} With mastoiditis occurring less commonly, physicians are less likely to consider the diagnosis, especially when the clinical picture has been masked by antibiotic therapy or when the process is chronic and of low grade. Appropriate antibiotic therapy, often accompanied by surgical drainage, can halt and prevent serious complications if mastoiditis is diagnosed early.

HISTORY

Before the advent of antibiotics, mastoiditis was a frequent complication of otitis media that could be treated only by expectant waiting or surgery.^{46,53} The first surgical opening of the mastoid cavity was performed in 1736 by Petit using a trepanation system. The trepanation system gave way to the chisel and gouge, which was then replaced by the electric drill, which was introduced at the end of the 19th century.⁶⁷ When surgery was used, many patients with mastoiditis were cured by simple mastoid drainage alone, with a mortality rate quoted at 2%.⁵³ Intracranial complications of mastoiditis carried a very grave prognosis, however. In the preantibiotic era between 1928 and 1933, 25 of every 1000 deaths at Los Angeles County Hospital in California were caused by intracranial complications of otitis media, such as meningitis, venous sinus thrombosis, and brain abscess. In contrast, between 1949 and 1954, only 2.5 per 1000 deaths at the same hospital were caused by complications of otitis or mastoiditis. The use of antibiotics in treating mastoiditis initially led to a marked decrease in the surgical approach to treatment of this illness.^{14,116} The realization that infection can persist and that complications of mastoiditis can occur even while the patient is receiving antibiotic therapy has resulted in the present-day approach of combined antibiotics and surgery, necessitating collaboration between the pediatrician and otolaryngologist.^{31,32,37,57,64,70,75,102,113}

ANATOMY AND PATHOPHYSIOLOGY

The mastoid process comprises the posterior part of the temporal bone and, as such, is adjacent to many important structures. Within the mastoid is an interconnecting system of air cells divided by bony septa that drain anteriorly into the epitympanic recess of the middle ear via a narrow aditus.^{14,30} Only the superior portion of the mastoid airspace, the antrum, is present at birth; pneumatization of the mastoid starts

soon after birth and usually is completed by the time the child is 2 years of age.^{7,53} Structures lying anteromedial to the mastoid process include the middle ear and ossicles, the facial nerve, the posterior bony wall of the external auditory canal, the jugular vein, and the internal carotid artery. Posteromedially, the mastoid borders the posterior cranial fossa and the sigmoidal sinus. Superiorly, the mastoid borders the middle cranial fossa. Medially, the mastoid cortex encases the cochlea and semicircular canals. The soft tissues and muscles of the lateral neck are located inferiorly. Any or all of these adjacent structures can be affected by extension of a suppurative process in the mastoid.

A certain amount of mastoid inflammation accompanies all cases of otitis media because the mastoid airspaces are continuous with the middle ear cavity, and both are lined by a continuous mucoperiosteum.^{7,30} The first stage of an ear and mastoid infection is associated with hyperemia of the middle ear and the mastoid air cell mucosa. If the infection persists, an exudative stage develops, with serum, fibrin, polymorphonuclear cells, and red blood cells accumulating in the middle ear and mastoid. The accumulation of purulent exudate increases the middle ear pressure, eventually resulting in perforation of the tympanic membrane, followed by drainage of mucopurulent matter from the middle ear and mastoid air cells. Some children also have such marked mucoperiosteal swelling that the drainage of pus from the mastoid is blocked, causing aditus blockade. The pus under pressure creates an environment of local acidosis, hypoxia, and ischemia, causing decalcification and resorption of the bony septa. The term *coalescent mastoiditis* is applied to this process because, with the destruction of the bony septa, the mastoid air cells coalesce into large cavities. Osteomyelitis of the adjacent bone may develop, with subsequent bony erosion and eventual extension of the infection into surrounding structures.^{7,30}

Congenital cholesteatomas usually manifest as a “squamous pearl” in the anterosuperior quadrant of the middle ear, abutting the tympanic membrane. They may be associated with recurrent otitis media.⁶¹ Acquired cholesteatomas often are a result of chronic infections and tympanic membrane perforation. The perforation allows for squamous material from the external auditory canal to enter the middle ear space (medial migration or Habermann’s theory).⁸⁰ This tissue contains osteolytic enzymes, leading to bony erosion or mastoid air cell obstruction.⁷¹ Cholesteatomas also may cause slow, insidious erosion of underlying bone, predisposing the patient to extramastoid spread of infection months or years later.^{30,86}

MICROBIOLOGY

The bacteriologic findings in 12 studies of acute mastoiditis and one study of chronic mastoiditis are presented in Table 17.1. These studies,

which were all carried out in the antibiotic era, span a 61-year time period and occurred in seven countries.* In all studies the leading causative agent in acute mastoiditis is *Streptococcus pneumoniae*; surprisingly the second organism of importance is *Streptococcus pyogenes*.†

Other organisms of importance in acute mastoiditis are *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*. Because nontypable *H. influenzae* is a very common cause of otitis media, it is surprising that this agent is not more commonly recovered in acute mastoiditis. Similarly, *Moraxella catarrhalis*, another common cause of otitis media, is rarely found in association with acute mastoiditis.⁵²

Also, because neither *S. aureus* nor *P. aeruginosa* is a cause of acute otitis media it is likely that these agents, when isolated in acute mastoiditis, are secondary rather than primary pathogens. The same is likely for coagulase-negative staphylococci and various anaerobic organisms. However, in contrast to *S. aureus* and *P. aeruginosa*, if coagulase-negative staphylococci and anaerobic organisms are present they may be contaminants and may not contribute to the infectious process.

An increased incidence of penicillin-resistant *S. pneumoniae* infections has occurred during the past 25 years, leading to a higher likelihood of mastoiditis being a complication of otitis media.^{13,74,76,114} The percentage of pneumococcal mastoiditis caused by penicillin-resistant strains increased from 25% to 44% between 1994 and 1998, without an increase in the total number of cases of pneumococcal mastoiditis.⁴³ Pneumococcal conjugate vaccine (PCV7) was introduced into the pediatric immunization schedule in 2000 and, over the ensuing decade, invasive pneumococcal disease decreased dramatically (see Chapter 85). PCV7 contains the serotypes 14, 6B, 19F, 18C, 23F, 4, and 9V. Surprisingly, in a large study performed by Choi and Lander,¹³ the number of admissions for mastoiditis at an urban tertiary care children's hospital did not decrease in the PCV7 vaccine era. In fact, the post-PCV7 patients had more severe disease compared with patients seen between 1996 and 2002.

Ongkasuwan and associates⁷⁶ studied 41 cases of pneumococcal mastoiditis between 1995 and 2007. In the pre-PCV7 era (1995–99) there were 12 cases, and none was caused by the nonvaccine serotype 19A. Between April 2000 and October 2005, there were 15 cases of pneumococcal mastoiditis, and 5 of these cases were due to pneumococcal serotype 19A. In their last time period (November 2006 to June 2007), there were 14 cases, and all were due to serotype 19A. Sixty-eight percent of the serotype 19A isolates had multidrug antibiotic resistance.

In the post-PCV7 era, Giannakopoulos and associates²⁸ noted that nonvaccine genotype 19A was found in more than half of their mastoiditis cases. In Colorado, Halgrimson and colleagues³⁴ noted a significant decline in acute mastoiditis cases after the introduction of PCV7. This decline was short-lived, however, with a return to pre-PCV7 rates. In Israel, Amir and coworkers¹ noted an increase of acute mastoiditis caused by *S. pyogenes* between the early 1990s and 2003–09. In another study in Israel, it was noted that there was no overall reduction in acute mastoiditis or in pneumococcal acute mastoiditis in the era of pneumococcal conjugate vaccines.⁴⁹ PCV13, the 13-valent pneumococcal conjugate vaccine, was introduced in 2010. Most recently, Tawfik and colleagues¹¹⁷ used cross-sectional data from the Healthcare Cost and Utilization Project Kids' Inpatient Database to look at the annual prevalence of hospital admission for acute otitis media and its associated complications (acute mastoiditis, suppurative labyrinthitis, or acute petrositis) for the years 2000, 2003, 2006, 2009, and 2012. They found a significant reduction in the national prevalence rates of hospital admission for acute otitis media and its associated complications for all children younger than 21 years from 3.956 to 2.618 per 100,000 persons. The most significant declines were seen between 2000 and 2003 and between 2009 and 2012.

In 2013, Yarden-Bilavsky and associates¹¹² noted seven cases of acute mastoiditis due to *Fusobacterium necrophorum*. The illnesses in these seven young children were quite fulminate and resulted in prolonged hospitalizations.

The bacteriologic spectrum of chronic mastoiditis differs from that of acute mastoiditis. Aerobic cultures of chronic mastoiditis and chronic otitis media show predominantly *S. aureus* and gram-negative bacilli, especially *P. aeruginosa*.^{9,20,86} In addition, a wide variety of anaerobic organisms can

FIG. 17.1 An 18-month-old child with right-sided mastoiditis and proptotic right auricle.

be isolated from an infected mastoid and middle ear.^{9,20} Brook⁹ studied the aerobic and anaerobic bacteriology of chronic otitis media (of ≥ 3 months' duration) in 24 children. Anaerobic isolates alone were found in 17%, aerobic organisms alone were found in 4%, and mixed aerobic and anaerobic infections were found in 79%. All cases had from two to seven different bacterial isolates. *Peptococcus* spp., *Actinomyces* spp., and *Bacteroides melaninogenicus* (*Prevotella melaninogenica*) were the most commonly isolated anaerobic organisms. Seventeen patients were infected with β -lactamase-producing organisms (i.e., *S. aureus* or *P. melaninogenica*, *Bacteroides fragilis*, or other *Bacteroides* spp. that were resistant to ampicillin).

Mycobacterium tuberculosis currently is an uncommon cause of mastoiditis in the United States but continues to be a cause of chronically draining ears in lower socioeconomic groups and immigrants from endemic areas.^{10,65,68} Case reports of mastoiditis implicate such organisms as nontuberculous mycobacteria,^{59,73} *Turicella otitidis*,^{90,96} *Aspergillus fumigatus*,³⁵ *Paragonimus*-like trematodes,⁷⁸ *Nocardia asteroides*,⁶³ *Actinomyces* spp.,¹⁰¹ *Blastomyces dermatitidis*,⁴³ and *Histoplasma capsulatum*.⁶³ *Pneumocystis jiroveci* otitis media and mastoiditis have occurred as the first manifestation of acquired immunodeficiency syndrome.²⁶

CLINICAL PRESENTATION

The classic presentation of acute mastoiditis is a febrile child with ear pain, postauricular swelling, and postauricular tenderness developing days to weeks after the beginning of development of acute otitis media (Fig. 17.1).^{2,25,29,33,70,75,114} If antibiotics were used to treat acute otitis media, the child may have seemed to improve only to become ill again while still receiving therapy or after the antibiotics were stopped; conversely, the inflammation may not have responded to the antibiotics at all. Examination of the tympanic membrane in acute mastoiditis usually shows that it is abnormal.^{29,37,70} Early in the course of illness, periosteal inflammation produces swelling and tenderness and sometimes redness over the mastoid process.^{7,29} Palpable postauricular fluctuance occurs later, when pus from the mastoid air cells breaks through the underlying bony cortex and forms a subperiosteal abscess.³⁶ In children older than 1 year of age, the most common area where fluctuance is felt lies behind the ear, where it pushes the earlobe up and out; however, in children younger than 1 year, the fluctuance often may occur above the ear, pushing the pinna down and out.²⁹

Mastoiditis has occurred in children with cochlear implants. Zawawi and colleagues¹¹⁵ reviewed all publications and noted 43 children who had cochlear implants and who subsequently developed acute mastoiditis. They observed that with proper treatment (intravenous antimicrobials and surgery) the implants did not need to be removed in all but one instance.

Chronic mastoiditis is a much more indolent disease process than acute mastoiditis. It develops when long-standing middle ear disease, usually having a duration of months to years, has been present.⁸⁶ Fever and postauricular swelling may or may not be present. Persistent or intermittent drainage of mucopurulent matter from a previously

*References 4, 9, 25, 28, 29, 34, 40, 70, 75, 82, 89, 97, 114.

†References 4, 25, 29, 34, 37, 40, 51, 52, 70, 75, 82, 89, 97, 114.

perforated eardrum suggests chronic mastoiditis. Hearing loss and ear pain also may accompany chronic mastoiditis.⁸⁶ All these symptoms can be mild enough to be ignored until serious intracranial suppuration occurs. Persistent ear drainage, persistent ear pain, or an otitis media nonresponsive to antibiotics should prompt a search for mastoiditis.

COMPLICATIONS

Complications of mastoiditis include subperiosteal abscess,³⁶ Bezold abscess,^{22,62,92} facial nerve paralysis,^{18,105,106} meningitis,^{14,29} brain abscess,^{12,14,29,42,93} cerebellar abscess,⁷ epidural abscess,⁷ subdural empyema,⁸ labyrinthitis,^{30,77} venous sinus thrombophlebitis,^{5,17,27,47,79,85,91,108} bacteremia,^{14,64,77} benign intracranial hypertension,⁸ osteomyelitis of the temporal bone with occasional extension to adjacent bones,^{7,30} hearing loss,⁸¹ septic pulmonary emboli,⁴¹ and cerebrospinal fluid otorrhea.³⁰ Subperiosteal abscesses appear as a postauricular fluctuant mass that obscures the postauricular sulcus. They occur when pus in the mastoid breaks through the bony cortex or extends along vascular channels and dissects under the overlying periosteum.³⁶

A Bezold abscess develops when a mastoid infection erodes through the bony cortex of the inferior aspect of the mastoid tip and dissects down the tissue planes to form a deep neck abscess. Fluctuance over the mastoid is not felt. Rather, swelling and tenderness are present below the mastoid process and under the sternocleidomastoid muscle.²²

The facial nerve runs through the mastoid and the middle ear, rendering it vulnerable to injury when extension of mastoid or middle ear infection occurs.³⁰ Pressure on and inflammation of the facial nerve from symptomatic or asymptomatic mastoiditis can lead to transient or permanent facial nerve paralysis that usually is unilateral, although bilateral facial palsy from mastoiditis can occur.^{7,105,106}

Because the temporal bone that houses the mastoid air cells constitutes the floor of the middle and posterior cranial fossae, bony erosion from osteomyelitis, preexisting bony defects, or spread of infection along vascular channels can allow for intracranial spread of mastoid infections into the middle and posterior cranial fossae. The infection may remain confined to the extradural space as an extradural abscess, or it may penetrate the dura and produce a subdural empyema, a brain abscess, a cerebellar abscess, or meningitis.^{7,30}

Invasion of infection into the bony labyrinth through the oval or round window triggers labyrinthitis. Initial tinnitus, hearing loss, nausea, and dizziness progress to severe vertigo, ear pain, vomiting, nystagmus, and difficulties with balance.³⁰

Intracranial venous sinus thrombophlebitis is a rare but potentially fatal complication of mastoiditis.* The lateral aspect of the sigmoid sinus is formed by the temporal bone. Venous sinus thrombophlebitis results when an underlying mastoiditis extends through the temporal bone in close proximity to the lateral or sigmoid venous sinus. A perisinus abscess initially is formed, followed by formation of a mural thrombus in the sinus wall. The thrombus eventually may occlude the entire sinus, or it may suppurate and spread along the sinus, resulting in septicemia, increased intracranial pressure, septic emboli, and extension of infection to other intracranial structures.^{17,23} The classic findings of septic thrombosis of the lateral sinus are “picket fence” spiking fevers, shaking chills, and tenderness along the jugular vein associated with acute or chronic otitis. A palpable “cord” at the jugular vein (indicating a jugular vein thrombus) also may be present. When only a perisinus abscess is present, or if the patient is being treated partially with antibiotics, the only features may be a low-grade fever and headache.^{32,103}

Benign intracranial hypertension can be seen in association with lateral sinus obstruction involving the torcular and sagittal sinus secondary to mastoiditis and is termed *otitic hydrocephalus*. Rarely otitic hydrocephalus can be seen with mastoiditis in the absence of lateral sinus thrombosis. The decreased venous drainage caused by the venous sinus obstruction results in increased intracranial pressure, headache, papilledema, and sixth nerve palsy without enlarged ventricles or a space-occupying lesion.^{30,32}

Permanent conductive hearing loss occurs when the middle ear mastoid infection is severe enough to damage or destroy the ossicles.

Tuberculous mastoiditis classically manifests as marked conductive hearing loss that often is irreversible.⁵⁸

Osteomyelitis secondary to mastoiditis can spread to adjacent bones. Involvement of the petrous portion of the temporal bone produces a syndrome, described by Gradenigo in 1907, with a triad of abducens paralysis or paresis, severe pain in the distribution of the trigeminal nerve, and suppurative otitis media; this is known as Gradenigo's syndrome or petrous apicitis, and additional cranial nerve deficits also may occur.^{11,57,89}

Antibiotics may mask the classic signs of petrositis and allow progression to severe intracranial complications, such as meningitis and epidural abscess. Petrositis may be suspected only when antibiotic and surgical management for mastoiditis fails to control chronic ear drainage.³⁰

M. tuberculosis mastoiditis is an uncommon finding but should be considered in children who have chronic ear discharge despite having received antibiotic therapy.^{58,65} Children can go for months or years with chronically draining ears before the diagnosis of tuberculous mastoiditis is considered.^{10,68} Children from lower socioeconomic homes, immigrants from endemic areas, and children with tuberculosis contacts in the family are at risk. The classic presentation in the preantibiotic era was an afebrile young child with painless persistent watery ear drainage, an enlarged preauricular lymph node, a history of contact with a person with tuberculosis, and often facial nerve paralysis.^{94,107}

Tuberculous mastoiditis is not always painless.¹¹¹ Sometimes the diagnosis initially is suspected only when a mastoidectomy wound does not heal.^{55,86} Early in the course of the disease, physical examination may reveal small yellow spots (caseating granulomas) on a thickened and hyperemic tympanic membrane. These spots coalesce early and produce multifocal tympanic membrane perforations.⁵⁵ The discharge through these perforations initially is watery, but later it becomes purulent.⁵⁴ Pale, avascular granulation tissue is abundant throughout the middle ear and mastoid and often is seen in the external auditory canal and around the tympanic membrane perforation.^{10,94,111} Preauricular and postauricular nontender, enlarged lymph nodes may be present,^{54,63} and early and severe hearing loss is characteristic.¹¹¹ Often, there is evidence of tuberculosis elsewhere in the body.¹¹¹ A tuberculin skin test usually, but not always, is positive.⁶⁸

DIFFERENTIAL DIAGNOSIS

Postauricular swelling, a chronically draining ear, or radiographic evidence of mastoid abnormalities also can appear in other disease entities. Postauricular lymphadenopathy can occur secondary to a scalp infection, causing postauricular swelling. The swelling is discrete, does not displace the pinna, and does not obliterate the postauricular sulcus.²⁹ Severe otitis externa may lead to periauricular cellulitis, with postauricular swelling, erythema, and tenderness.^{6,39} Mumps can cause parotid swelling, pushing the earlobe up and out, but the swelling is over the parotid gland rather than located postauricularly. Histiocytosis,^{48,60} acute lymphocytic leukemia,⁶⁹ acute myelogenous leukemia,^{48,104} Burkitt lymphoma,¹⁰⁹ non-Hodgkin lymphoma,⁴⁴ aneurysmal bone cysts,¹⁶ and other benign and malignant tumors of the mastoid bone¹⁵ also can manifest as symptoms clinically suggestive of mastoiditis. Kawasaki disease may mimic acute mastoiditis with postauricular lymph node swelling and ear pain.⁸⁸ Children with severe and recurrent ear infections may have an underlying congenital or acquired immunodeficiency.

SPECIFIC DIAGNOSIS

The diagnosis of mastoiditis can be made on clinical grounds alone when a child has an acute episode of fever, otitis media, and posterior auricular tenderness and fluctuance. Temporal bone computed tomography (CT) always is recommended to confirm the diagnosis and assess for coalescence. Mastoiditis is much less likely when swelling and tenderness over the mastoid process are absent, such as when an infection has been masked by antibiotic treatment or when it has extended to an area other than over the mastoid process. Mastoiditis needs to be considered in all cases of otitis media not responding to antibiotics and in all intracranial suppurative diseases that do not have an apparent focus.

Obtaining an aspirate from the middle ear is an important part of properly diagnosing and managing mastoiditis. Gram stains of aspirates from the middle ear are quite accurate and, as such, can help in the

*References 5, 7, 27, 30, 47, 77, 79, 85, 91, 103, 108.

initial selection of antibiotic therapy for chronic mastoiditis. Brook⁹ found that in 24 children with tympanocentesis, half of the Gram stains showed a complete correlation with subsequent culture results, and the other half showed a partial correlation (one bacterial species was not seen). Leukocytes were seen on all the Gram stains. In addition, cultures from the middle ear accurately reflect mastoid disease.^{29,64}

Ginsburg and associates²⁹ compared the results of cultures of middle ear aspirates and mastoid cultures in 16 patients with acute mastoiditis and found that the same bacterial species was isolated from both sites. A sterile aspiration through an intact tympanic membrane gives the most accurate culture information. If the tympanic membrane is perforated, the purulent drainage may be contaminated by colonizing ear canal flora. An aspirate for culture generally should be obtained from the ear drainage, preferably from as close to the perforation as possible. Aspiration of postauricular fluctuance also is useful in identifying the responsible organisms.^{36,75} In addition, specimens should be obtained directly from the mastoid at surgery. All of them should be sent for aerobic and anaerobic cultures with proper anaerobic transport technique. If the child has had a chronic ear infection, or if the child is in a high-risk population for acquiring tuberculosis, mycobacterial stains and cultures also should be obtained and a tuberculin skin test should be placed or a serum immunologic-based tuberculosis test should be performed.

A lumbar puncture should be performed if the clinical presentation suggests meningeal irritation. A CT scan should be obtained before performing the lumbar puncture if papilledema or a suggestion of focal intracranial extension is present. Lymphocytosis of the cerebrospinal fluid suggests a parameningeal focus of infection. An immunologic evaluation should be considered if a child has had recurrent episodes of otitis media leading to mastoiditis.

Peripheral white blood cell counts in mastoiditis may be normal or elevated, often with an increase in band-form neutrophils.^{37,70} The erythrocyte sedimentation rate often is elevated in acute mastoiditis, but it usually is normal in chronic mastoiditis.⁸¹

When a patient is not improving on medical therapy, radiologic imaging of the temporal bone is needed. Changes in the temporal bone are seen best on a CT scan.⁹⁹ Early in the course of mastoiditis, nonspecific clouding of the middle ear and mastoid is seen. With time, necrosis and coalescence of the bony septa occur. Other CT findings in mastoiditis include hypoaeration of the mastoid and adjacent bony destruction. A CT scan of a child with unilateral mastoiditis complicated by lateral sinus thrombosis and elevated intracranial pressure is shown in Fig. 17.2. Magnetic resonance imaging is valuable to search for suppurative intracranial complications of mastoiditis.^{84,98,99} In addition, sometimes magnetic resonance angiography or venography (or both) is indicated to diagnose sigmoidal sinus thrombosis.¹⁵

TREATMENT

Medical and surgical treatments differ for acute versus chronic mastoiditis. For acute mastoiditis, the mainstay of treatment is antimicrobial therapy. The initial choice of antibiotics is made empirically after appropriate cultures have been obtained. To address the most common causes of acute mastoiditis (*S. pneumoniae*, *S. pyogenes*, *S. aureus*, and *H. influenzae*), cefepime 150 mg/kg per day given every 8 hours or cefotaxime 200 mg/kg per day divided every 6 hours or ceftriaxone 100 mg/kg per day given every 12 hours and vancomycin 60 mg/kg per day divided every 6 hours are reasonable initial choices. Antibiotic therapy for acute bacterial mastoiditis should conform to the principles of therapy for osteomyelitis in that treatment is begun with intravenous antibiotics with continuation of long-term intravenous therapy only in those cases with intracranial extension with an organism for which no effective oral antibiotic exists (e.g., *P. aeruginosa*). Otherwise, after several days to a week, most patients respond well clinically and in some instances are transferred to high-dose oral antibiotic therapy.⁶⁶ Total duration of therapy should be based on clinical response and the normalization of the white blood cell count, sedimentation rate, and the C-reactive protein value. Usually minimum therapy will be 3 weeks, but it may possibly last longer depending on severity of infection, complications, and what organism is isolated. Tailored antibiotic therapy to a specific cultured organism is ideal but not always possible, especially because many

FIG. 17.2 Computed tomography scan of the head of a 12-year-old boy with left lateral sinus thrombosis and increased intracranial pressure complicating left mastoiditis. The left mastoid air cells are opacified with marked loss of the fine bony septa, in contrast to the right mastoid air cells.

children with acute mastoiditis will have already undergone some form of outpatient antibiotic therapy.

All children with acute mastoiditis may potentially require surgical intervention in the form of myringotomy with pressure equalization tube placement and/or mastoidectomy; therefore it is imperative that pediatricians and otolaryngologists work together in treating mastoiditis.^{29,37,70,75,114} The timing and degree of surgical intervention for acute mastoiditis vary by center. Traditionally the mainstay of treatment of acute mastoiditis in children has been myringotomy with or without placement of ventilation tubes in conjunction with parenteral antibiotics as described earlier.^{24,56} This procedure is necessary for obtaining middle ear fluid cultures, for relieving pain, and for evacuating pus from the middle ear cavity.¹⁰⁰

Mastoidectomy refers to removing the infected and inflamed mastoid air cells, thereby eliminating the further multiplication and spread of infection. In acute mastoiditis, indications for more complete surgical intervention in the form of a mastoidectomy include postauricular fluctuance; facial nerve paralysis; nausea, vomiting, and vertigo suggestive of labyrinthitis; meningitis; brain abscess; venous sinus thrombosis with or without intracranial hypertension; epidural or subdural empyema; and petrositis. In addition, patients with acute mastoiditis treated initially with parenteral antibiotics and myringotomy who have progression of postauricular swelling, fever, otalgia, or purulent otorrhea should also undergo mastoidectomy.^{17,30,36,37,70,75,102} There is a growing trend toward upfront conservative management of pediatric mastoiditis with intravenous antibiotics and myringotomy and tube placement alone. Mastoidectomy is then reserved for cases that are nonresponsive to conservative measures and typically implemented within 3 to 5 days of presentation.⁸⁷ Mastoidectomy is also preferred in cases of unsuccessful drainage of a subperiosteal abscess as well as in the presence of intratemporal or intracranial complications.¹⁰⁰ One pediatric center in France published an algorithm for treatment of acute mastoiditis based on a series of 188 children treated between 2001 and 2008. Clinical acute mastoiditis at that center is treated initially with tympanocentesis or postauricular puncture under local anesthesia and parenteral broad-spectrum antibiotics with clinical reassessment at 48 hours. Mastoidectomy is performed only in patients who fail to improve on intravenous antibiotics alone, which

in this series was necessary in only 33% of cases.⁸⁹ Another retrospective review of 167 children admitted for acute mastoiditis in Athens between 2002 and 2010 had similar conservative management with parenteral antibiotics and myringotomy on admission. If no clinical improvement was appreciated, a cortical mastoidectomy was performed within 3 to 5 days. Rate of mastoidectomy was 42%, and no child developed any additional complications under this treatment schema.⁸⁷

Recently retroauricular puncture with tympanostomy tube placement has been advocated in lieu of a formal mastoidectomy, especially in cases of subperiosteal abscesses, because it has been shown to be effective in limiting the number of mastoidectomies performed and shortening the hospital stay.⁴ Surgical treatment should always include culture of the middle ear or mastoid, which is becoming increasingly important as penicillin-resistant pneumococci and methicillin-resistant staphylococci have become more widespread.^{3,21,38,45,72,83,110} In addition, during the mastoidectomy, inflammatory tissue should always be sent for histologic evaluation to exclude the rare case of eosinophilic granuloma or rhabdomyosarcoma, which can present similarly to acute mastoiditis.

In children with acute mastoiditis secondary to a cholesteatoma, modified radical mastoidectomy with removal of the cholesteatoma should be performed. In most cases, a “second-look” operation 6 to 9 months later is performed to ensure complete eradication of squamous epithelium from the middle ear cleft and mastoid.

Preoperative audiograms should also be obtained in all children with mastoiditis to assess for conductive versus sensorineural hearing loss, both of which can occur with acute and chronic mastoiditis.

The antimicrobial and surgical treatment in chronic mastoiditis differs from acute mastoiditis. By definition, symptoms have been present for longer than 1 month in children with chronic mastoiditis. In these children, *S. aureus*, gram-negative bacilli (especially *P. aeruginosa*), and anaerobes are seen more frequently (see Table 17.1). Therefore, combination broad-spectrum intravenous antibiotics are recommended. An aminoglycoside such as gentamicin 7.5 mg/kg per day divided every 8 hours can be administered for coverage of gram-negative bacilli; a semisynthetic penicillin such as piperacillin-tazobactam 200 to 300 mg/kg per day divided every 6 hours can be used to cover *P. aeruginosa* (synergistic with gentamicin), anaerobes, and methicillin-sensitive *S. aureus*; and vancomycin (60 mg/kg per day divided every 6 hours) can cover for resistant *S. aureus* and pneumococci. As with cases of acute mastoiditis, antibiotic therapy is tailored according to culture results from the middle ear or mastoid. In cases of intracranial extension caused by *P. aeruginosa*, cefepime 150 mg/kg per day divided every 8 hours is recommended because of its improved penetration of cerebrospinal fluid.

Indications for surgical intervention in patients with chronic mastoiditis include all of the indications for acute mastoiditis, with the addition of patients who have persistent chronic otorrhea with bony changes on radiographs. Complete mastoidectomy is advocated in these children because of the duration and therefore likely extent of diseased mastoid and middle ear mucosa. The presence of a middle ear cholesteatoma should always be suspected, especially in patients with chronic unremitting otorrhea.

In the unusual case of *M. tuberculosis* mastoiditis, antituberculous chemotherapy should be started in a manner similar to treatment of bony tuberculosis (see Chapter 96). It is also important to remember the possibility of underlying immunodeficiency in children with mastoiditis who demonstrate a slow response to medical and surgical therapy.

The treatment of complications of acute and chronic mastoiditis needs to be tailored to the specific complication. Treatment of subperiosteal abscesses includes postauricular needle aspiration under local anesthesia, incision and drainage under local anesthesia with placement of a surgical drain, intravenous antibiotics and myringotomy, and/or mastoidectomy. More recent series have advocated the more minimally invasive treatments under local anesthesia, citing a 92% improvement rate without the complications of mastoidectomy.¹⁰⁰ A Swedish retrospective study found that retroauricular needle aspiration and/or incision with intravenous antibiotics and myringotomy was an effective first-line treatment for subperiosteal abscess without any greater risk of complications and a shorter overall hospital stay compared to those treated with mastoidectomy.¹⁹ Treatment of a Bezold abscess requires surgical drainage in addition to intravenous antibiotics.

When facial nerve paralysis occurs, treatment consists of myringotomy with pressure equalization tube placement along with parenteral antibiotics. In cases of complete facial paralysis, a mastoidectomy is thought to be beneficial.¹⁸

Otogenic meningitis is treated similarly to other forms of meningitis (see Chapter 31). Mastoidectomy is theoretically beneficial, although not urgent, and is infrequently performed.

In intracranial abscesses, in addition to intravenous antibiotics, surgical treatment should consist of a complete mastoidectomy because the confinement of the infection in the middle ear and mastoid allows for the disease to spread beyond the confines of the mastoid bone. Intracranial drainage either from the mastoid route or via a formal craniotomy should also be done.⁵⁰ Small, multifocal, or inaccessible intracranial lesions can be treated with antibiotics alone with a mastoidectomy⁴² (see also Chapter 32).

Treatment of lateral sinus thrombosis includes long-term antibiotics, pressure equalization tube placement, and mastoidectomy to remove the nidus of infection with either needle aspiration of the sinus or thrombectomy. The use of anticoagulation for otogenic lateral sinus thrombosis is controversial and determined on an individual basis. Children who develop lateral sinus thrombosis should be evaluated for an underlying hypercoagulable state. Although rare, it is essential to consider lateral sinus thrombosis in any child with a recent history of otomastoiditis presenting with headaches and/or neurologic deficits. A retrospective case series and literature review showed that 85% of patients with acute otogenic lateral sinus thrombosis were treated with mastoidectomy, and 96% of patients received some duration of anticoagulation. Among these patients, 88% had complete clinical recovery even though clot resolution was only demonstrated in 35% of them, suggesting that venous recanalization may not be necessary for recovery.⁹⁵

PROGNOSIS

The prognosis for mastoiditis depends on the extent of the infection and the causative organism. Mastoiditis that is treated adequately early in the course of illness before the onset of intracranial extension has a very good prognosis. Facial nerve paralysis is reversible early on,^{94,105} and benign intracranial hypertension resolves with treatment of the mastoiditis.³⁰ Permanent neurologic deficits and death may occur if mastoiditis extends to cause meningitis, brain abscesses, epidural abscess, subdural empyema, or venous sinus thrombophlebitis. Symptoms of mastoiditis may recur if antibiotic therapy is of insufficient duration or if surgical debridement of an infected bone or of an infected cholesteatoma is inadequate. Sensorineural and conductive hearing deficits are reversible early on in mastoiditis; however, chronic infection may produce irreversible hearing loss.

PREVENTION

Early adequate antibiotic treatment of otitis media reduces significantly a child's risk for developing mastoiditis. In addition, rapid treatment of known mastoiditis along with early investigation of persistent ear drainage, persistent ear pain, or an otitis media that is not responding to antibiotic management decreases the risk for developing suppurative complications associated with mastoiditis.

Croup (Laryngitis, Laryngotracheitis, Spasmodic Croup, Laryngotracheobronchitis, Bacterial Tracheitis and Laryngotracheobronchopneumonitis) and Epiglottitis (Supraglottitis)

18

Leidy Johana Tovar Padua • James D. Cherry

The term *croup* is used to identify several different respiratory illnesses characterized by varying degrees of inspiratory stridor, cough, and hoarseness resulting from obstruction in the region of the larynx. The etiology of croup syndromes is diverse, and the consideration of noninfectious possibilities in the differential diagnosis is of major importance. [Box 18.1](#) classifies etiologic considerations in supraglottic, laryngeal, and infraglottic acute obstructions.

Croup is discussed under the subheadings of laryngitis, laryngotracheitis, spasmodic croup, laryngotracheobronchitis, bacterial tracheitis, and laryngotracheobronchopneumonitis. Diphtheric croup is presented in Chapter 90.

Epiglottitis (supraglottitis) is an illness characterized by inflammation and edema of the epiglottis and frequently also of the arytenoepiglottic folds and ventricular bands at the base of the epiglottis.⁷⁸ Until the present *Haemophilus influenzae* type B vaccine, era this disorder was usually caused by *H. influenzae* type B and was mainly a disease of children. The illness is characterized by rapid onset and progression, and, without treatment, death caused by obstruction of the airway occurs. Epiglottitis in children is a pediatric otolaryngologic emergency.

HISTORICAL ASPECTS

The word *croup* is derived from the Anglo-Saxon word *kropan*, “to cry aloud.”⁸² Until the 20th century, most crouplike illnesses were thought to be diphtheria. Diphtheritic croup is an ancient disease that has been traced to the time of Homer. The historical trail of diphtheria disappeared in the 5th century and did not reappear until 1100 years later. In the 16th century, epidemics were noted in Europe. [Top](#)⁴³⁸ credits Bretonneau with differentiating diphtheritic croup from spasmodic croup in 1826. In the middle third of the 20th century, the history of croup was marked by three important events: (1) the rapid decline in incidence of diphtheria

associated with the use of toxoid, (2) the introduction and widespread use of antibiotics, and (3) the advent of tissue culture techniques, resulting in the establishment of viruses as etiologic agents. After these three events occurred, a prevalent academic view was that all croup was of viral etiology, and bacteria generally were dismissed as causative agents.^{83,97,133,348} However, a careful review of many publications from the first half of the 20th century indicates a causative role for several bacteria, in addition to *Corynebacterium diphtheriae*, in croup.* Bacterial croup (bacterial tracheitis) was rediscovered in 1979.[†]

In the 1940s, Davison¹⁰⁹ separated spasmodic croup from other, more severe forms of croup. The clinical and pathologic aspects of this entity were poorly defined, and today it often is not separated clinically from more severe forms of croup.

The early history of epiglottitis is obscure, probably because of the importance of diphtheritic croup.⁸² In 1887, Baron²⁰ described in detail a 30-year-old woman with epiglottitis who recovered after treatment with hot poultices and steam with tincture of benzoin. In 1900, Theisen⁴³⁷ described three cases in the United States. Not until the early 1940s did acute epiglottitis become recognized as a definite clinical entity caused by *H. influenzae* type B.^{5,31,400} In 1948, Rabe,³⁴⁷ in a study of 347 children with “infectious croup,” presented evidence for the division of the clinical illness into three etiologic categories—diphtheritic croup, viral croup, and *H. influenzae* type B croup (acute epiglottitis). Since the early 1990s, a dramatic decrease in the number of cases of epiglottitis has occurred in many countries because of the widespread use of *H. influenzae* type B conjugate vaccines.[‡]

TABLE 18.1 Classification and Definition of Infectious Illnesses Involving the Larynx and Supraglottic and Infraglottic Regions

Category	Other Terms	Definitions
Supraglottitis	Epiglottitis	Infection of the epiglottis and/or arytena-epiglottic folds and ventricular bands of the base of the epiglottis resulting in swelling and upper airway obstruction
Laryngitis		Inflammation of larynx resulting in hoarseness; usually occurs in older children and adults in association with common upper respiratory viral infections
Laryngeal diphtheria	Membranous croup, true croup, diphtheritic croup	Infection involving larynx and other areas of upper and lower airway due to <i>Corynebacterium diphtheriae</i> resulting in gradually progressive obstruction of airway and associated inspiratory stridor
Laryngotracheitis	False croup, virus croup, acute obstructive subglottic laryngitis	Inflammation of larynx and trachea most often caused by infection with parainfluenza and influenza viruses
Laryngotracheobronchitis and laryngo-tracheobronchopneumonitis	Membranous laryngotracheobronchitis, pseudomembranous croup	Inflammation of larynx, trachea, and bronchi or lung or both; usually similar in onset to laryngotracheitis but more severe illness; bacterial infection frequently has causative role
Bacterial croup	Bacterial tracheitis, membranous croup, membranous tracheitis, membranous laryngotracheobronchitis, pseudomembranous croup	Severe form of laryngotracheitis, laryngotracheobronchitis, or laryngo-tracheobronchopneumonitis due to bacterial infection
Spasmodic croup	Spasmodic laryngitis, catarrhal spasm of the larynx, subglottic allergic edema	Illness characterized by sudden onset at night of inspiratory stridor; associated with mild upper respiratory infection without inflammation or fever but with edema in subglottic region

TERMINOLOGY

The terminology and classification of infectious illnesses involving the larynx and supraglottic and infraglottic regions have evolved over time. Classifications often have mixed etiologic categories with anatomic systems and have led to confusion. Croup often has been presented in articles under the heading of *laryngotracheobronchitis* when the authors actually were discussing laryngotracheitis and spasmodic croup.^{85,229,279,298,342,367,402,432} The term *membranous croup* has been used as the title for articles dealing with bacterial croup^{114,185} This use is confusing because membranous croup historically was diphtheria. Many articles dealing with bacterial croup also have been titled *bacterial tracheitis*.^{*} This term seems inappropriate because most cases of bacterial

croup seen today have lower respiratory tract involvement in addition to tracheal findings. Table 18.1 lists the classifications and definitions used in this chapter.

ETIOLOGY OF CROUP SYNDROMES

The etiologic agents in laryngitis, laryngotracheitis, spasmodic croup, laryngotracheobronchitis, and laryngotracheobronchopneumonitis are presented by frequency and severity of illness in Table 18.2. Laryngitis is a common manifestation of infection with many respiratory viruses in older children, adolescents, and adults. Outbreaks of laryngitis in closed population groups (e.g., boarding schools and military training camps) most frequently are caused by adenovirus types 4 and 7, and community outbreaks most often are noted in association with epidemic influenza. Sporadic instances of laryngitis usually are caused by adenoviral infections. Laryngitis also has been reported in association with group A streptococcal infections; the incidence of this association has varied from 2% to 40%.^{51,308,447} Somenek and associates⁴¹⁴ described an 11-month-old boy with severe membranous laryngitis caused by methicillin-resistant *Staphylococcus aureus* (MRSA).

Generally accepted today is that acute laryngotracheitis and spasmodic croup, which rarely are differentiated clinically, are caused by infection with many different viruses. Although numerous studies of respiratory viral infection exist, almost no attempt has been made to delineate the differences in etiologic spectrum by severity of illness.

Parainfluenza virus type 1 is the most common cause of acute laryngotracheitis and is responsible for frequent and clearly delineated fall and winter epidemics. Croup with parainfluenza type 2 virus seldom is severe but occasionally is related to small outbreaks. Parainfluenza virus type 3 is a frequent cause of sporadic but severe illness.

The most severe laryngotracheitis has been noted in association with influenza A viral infections. Respiratory syncytial virus and several different adenoviruses frequently are isolated in croup. Generally these illnesses are not severe, but lower respiratory tract involvement occasionally is a problem. Laryngeal, tracheal, and bronchial involvement commonly occurs in measles.⁸³ Although rhinoviruses, *Mycoplasma pneumoniae*, enteroviruses, herpes simplex virus, and reoviruses have been associated with croup, they generally cause only minimal distress. However, O'Neil and associates³³² reported two immunocompetent children who presented with severe acute laryngotracheitis caused by herpes simplex virus. Croup has been noted in association with infection

with the novel coronavirus NL63, human bocavirus, and human metapneumovirus.^{16,25,86,361,421,450} Lee and Storch²⁶⁹ noted that coronavirus NL63 was a relatively common cause of severe croup. Recurrent croup may be due to infection with a human papillomavirus.⁴⁸⁴

Bacteria, other than *H. influenzae* in epiglottitis and *C. diphtheriae* in membranous croup, generally were dismissed as causative agents in croup until more recently.^{97,133,348} Many publications on laryngotracheobronchitis from the first half of the 20th century indicate a role for several common bacterial pathogens.* In 1979, bacterial croup was rediscovered,²²⁷ and numerous reports of this illness have been published since then.[†]

In the reports from the preantibiotic era, *Streptococcus pyogenes* was the pathogen implicated most frequently. Since 1979, *S. aureus* has been the agent implicated most commonly. Other important bacteria are *Streptococcus pneumoniae* and *H. influenzae*. More recently, *Moraxella catarrhalis* has been found to be the causative agent in several cases.^{35,137,233,478} In most instances, bacterial croup is likely to be the result of bacterial superinfection in viral disease.[‡] *Cryptosporidium* also has been recovered from the trachea of an infant with a subacute illness.¹⁸⁷

Noninfectious causes of crouplike illnesses include airway hemangioma²⁴⁰ and laryngeal or esophageal foreign bodies.^{172,209}

ETIOLOGY OF SUPRAGLOTTITIS

Acute supraglottitis in children in the prevaccine era almost always was caused by *H. influenzae* type B.[§] In 34 pediatric series in which blood cultures were performed in 1570 children, *H. influenzae* type B was recovered in 76%. Supraglottitis caused by other bacteria was rare. In the 1570 children with blood cultures, the following other organisms were recovered: *S. pneumoniae*, 3; *S. aureus*, 3; *Haemophilus parainfluenzae*, 2; *H. influenzae* type A, 1; *H. influenzae* nontypable, 2; and *Bacillus* spp. 1.

In countries where *H. influenzae* type B immunization is routine, supraglottitis is a rare illness in children. Nevertheless, cases still occur in association with some infectious agents. The following pathogens have been implicated in this regard: *S. pneumoniae*; *S. aureus*; *H. parainfluenzae*; groups A, B, C, and G streptococci; *Pseudomonas aeruginosa* (in a patient with severe combined immunodeficiency syndrome); nontypable *H. influenzae*; and *Bacillus* spp.^{19,30,34,127,212,260,262,275,282,328,366,403,408,471,481}

Candida tropicalis was isolated from the blood of a 3½-year-old girl with supraglottitis who had been the recent recipient of an autologous bone marrow transplant.⁴⁵⁹

Candida albicans was noted in a case in a newborn whose mother had vaginal candidiasis and in a 6-year-old boy with chronic mucocutaneous candidiasis.⁴ *Candida* spp. epiglottitis was noted in two children infected with human immunodeficiency virus (HIV),^{317,398} and *C. albicans* epiglottitis was observed recently in a 2-year-old girl who was immunocompromised as a result of receiving chemotherapy for a primitive neuroectodermal tumor.²⁹²

Necrotizing epiglottitis in a 5-year-old boy with hemophagocytic lymphohistiocytosis associated with a mixed infection (*Enterococcus faecalis*, *Eikenella corrodens*, *Prevotella melaninogenica*, and *Neisseria* spp.) has been described.²⁴⁸ Reed and colleagues³⁵⁴ described a 17-year-old boy with an aryepiglottic abscess associated with a mixed infection (*Capnocytophaga ochracea*, *Bacteroides stercoris*, and *P. melaninogenica*).

Since 2009 in England and Wales, there has been an increase in invasive meningococcal diseases due to capsular group W sequence type 11 complex.²⁶³ Between 2010 and 2013, there were five cases of epiglottitis due to this meningococcal complex. Lake and colleagues²⁶⁵ noted necrotizing epiglottitis due to nontoxicogenic *Corynebacterium diphtheriae* in a 3-year-old girl who had nondiagnosed lymphoblastic

leukemia. A 14-month-old girl with prolonged stridor and epiglottitis associated with a mixed infection with herpes simplex virus type 1, *H. influenzae*, *S. pneumoniae*, and *S. aureus* has been reported.³⁹⁴ A 16-month-old child with type 1 herpes simplex virus stomatitis complicated by stridor and respiratory distress had epiglottitis; his aryteno-epiglottic folds were edematous and covered with vesicular lesions resembling those in the oral mucosa.⁴⁴ An 18-year-old girl had supraglottitis that also was caused by herpes simplex virus.³⁰³ In addition, parainfluenza type 3 and influenza type B viruses were isolated from the nasopharynx of two children with supraglottic inflammation.¹⁷⁷ *Haemophilus paraphrophilus*²²⁸ was recovered from the epiglottic surface of a single patient, as was *M. catarrhalis* in another patient.⁴⁵³

In adults, *H. influenzae* type B also has been the major cause of epiglottitis, but other organisms occur more commonly in adults than in children.* In 1992, Daum and Smith¹⁰⁶ reviewed 474 published cases of epiglottitis in adults, 293 of whom had blood cultures performed; 79 of those cultures (27%) yielded *H. influenzae*. Of these positive cultures, 43 were *H. influenzae* type B; 35 isolates were not typed, and 1 isolate was not *H. influenzae* type B. Trollfors and associates⁴⁴³ in Sweden found that of blood cultures obtained from 185 of 356 (52%) adult patients, *H. influenzae* was isolated from 53%. Of these, 53 were *H. influenzae* type B, and the type of the remaining 45 was not known.

In Finland, Bizaki and coworkers³⁸ reviewed 308 adult cases of acute supraglottitis during the 2-decade period from 1989 to 2009. The incidence increased from 1.88 per 100,000 in the first decade to 4.73 in the second decade. The causative organisms were *S. pyogenes*, *S. pneumoniae*, *S. milleri*, staphylococci *Pseudomonas* spp., *H. influenzae*, and *C. albicans*.

S. pneumoniae was reported to be isolated from the blood of 18 adults with supraglottitis, 10 of whom were receiving immunosuppressive therapy or were infected with HIV-1,^{42,50,214,237,239,268,347,368,371,396} and *H. parainfluenzae* was isolated from the blood of 5 patients.^{87,147,287,385,463} In Denmark, between 1995 and 2002, *H. influenzae* type F was recovered from 13 cases of epiglottitis in adults.⁶² Numerous other infectious agents have been implicated in case reports of adults with supraglottitis.[†] These agents include *S. pneumoniae*, *H. influenzae* type b, *Aeromonas hydrophila*, *Pasteurella multocida*, *Kingella kingae*, *Klebsiella pneumoniae*, group A and B streptococci, *Bacteroides* spp., *Fusobacterium necrophorum*, *Vibrio vulnificus*, *Serratia marcescens*, *S. aureus*, *Neisseria meningitidis*, *Aspergillus* spp., herpes simplex virus, EBV parainfluenza virus type 2, and *M. tuberculosis* and *Histoplasma* spp.⁶⁶

Epiglottitis also can result from noninfectious causes. Hot foods and water can cause thermal epiglottitis, as can poisoning with corrosive agents, including cocaine alkaloid.^{29,238,256,257,264} Tsai and Wang⁴⁴⁴ noted acute epiglottitis in a 23-year-old man after receiving traditional Chinese *gua sha* therapy. Hereditary angioedema may manifest with findings typical of epiglottitis.³³⁰

EPIDEMIOLOGY OF CROUP

Croup accounts for approximately 15% of lower respiratory tract disease seen in pediatrics. In a large 11-year study in a pediatric practice in Chapel Hill, North Carolina, Denny and associates¹¹⁷ noted the incidence of croup by age and sex. The highest attack rate occurred in children 7 to 36 months of age. Few cases occurred after the sixth birthday. Hoekelman¹⁹⁸ studied the occurrence of illness prospectively in 246 full-term, first-born, well infants during their first year of life. Three infants (1.2%) had croup during the study year. The analysis of a pediatric practice with approximately 3000 active records and approximately 10,000 yearly visits of children younger than 5 years disclosed five cases of croup in a group of 50 consecutive hospitalized patients.⁵² Although croup occurs occasionally in older children, most cases occur within the first 3 years of life.^{117,133,142,367,392}

Croup occurs more commonly in boys than in girls.^{33,117,252,367,369,370} In a 6-year study in Alberta, Canada, involving 20,079 emergency department visits, 61.3% were boys.³⁶⁹ In the Chapel Hill study, an increase was noted in the number of croup cases beginning in September, with a peak in October and November, and then a decrease during the next 7-month period.¹¹⁷ In a 2-year emergency department study in Toronto involving 1700 cases, the peak month of visits and hospital admissions was found to be October.³⁹² Marx and associates²⁹¹ reviewed the National Hospital Discharge Survey data for hospitalizations for croup between 1979 and 1993. They also examined Centers for Disease Control and Prevention laboratory-based surveillance data and published reports with virus isolation studies. Major peaks in hospitalizations for croup occurred in October of odd-number years at the time of peak parainfluenza virus type 1 activity. Minor peaks in hospitalizations for croup occurred each year in February when influenza A, influenza B, and respiratory syncytial viral infections were common occurrences. Epidemic peaks of acute laryngotracheitis reflect community-wide activity with parainfluenza 1 and 2 viruses or influenza A or B outbreaks.^{117,167,291}

In the Alberta, Canada, study in 1990 to 2000 and 2004 to 2005, biennial trends were apparent.^{369,370} Peak emergency department visits for croup occurred in November for odd years and in February for the other years. For the odd years, the overall rate increased from 43.4/1000 in 1999 to 2000 to 49.6/1000 in 2003 to 2004. A similar increase was noted in the even years (30.9/1000 in 2000 to 2001 to 34.1/1000 in 2004 to 2005).

In the Toronto study, the time of the visit to the emergency department was analyzed.³⁹² The peak number of visits occurred between 10 PM and 4 AM. During this period, approximately 17% of the children seen were admitted to the hospital. In contrast, of children seen between noon and 6 PM, approximately 50% were admitted to the hospital. Quite similar findings were noted in Alberta in the 6-year period between 1999 and 2005.^{369,370} A study of croup hospitalizations in Ontario over 14 years from 1988 to 2002 noted a biennial mid-autumn peak and an annual summer trough throughout the entire study period.³⁹¹ A striking finding in this study was a marked decrease in hospitalizations for croup after the winter of 1993 to 1994. This decrease continued in linear fashion for the remainder of the study duration. The authors suggest that the decreasing trend in croup hospitalizations was likely due to the increasing use of corticosteroid treatment in patients who presented to emergency departments with croup.

Because croup is caused by the same viruses that cause other respiratory illnesses, the method of spread probably is similar for all (see discussion of the common cold in Chapter 7). In children, most spread involves close person-to-person contact, with large droplets of virus-containing nasal secretions being applied to the nose from the hands of the future host or by close-range airborne acquisition. Parainfluenza viruses are common causes of colds in adults, so older individuals with trivial illnesses may be the source of more severe childhood croup.

EPIDEMIOLOGY OF SUPRAGLOTTITIS

In the prevaccine era, the epidemiology of invasive *H. influenzae* type B disease varied markedly among population groups.^{460,461} Epiglottitis also differed by population group, but this variation was not related necessarily to the rate of overall *H. influenzae* type B invasive disease in the population. For example, among Alaskan Eskimos and Navajo Native Americans, whose risk for acquiring invasive *H. influenzae* type B disease was 4 to 10 times that of most other American populations, epiglottitis was not recognized among 295 patients with invasive *H. influenzae* type B illness.^{96,461}

Of *H. influenzae* type B invasive disease, the percentage of cases of epiglottitis varied markedly among localities. For example, in Israel, only 0.3% of invasive *H. influenzae* type B infections were epiglottitis, whereas in Ireland, Wales, northeast England, Australia (Sydney), and Denmark, the percentage of epiglottitis cases varied between 16% and 32%.^{101,146,203,254,296,345} In Minnesota and Dallas County, Texas, only 6% and 3%, respectively, of invasive *H. influenzae* type B infections were epiglottitis.³¹⁴ In contrast with these findings in the United States, Europe, and Australia, the most common manifestation of invasive *H. influenzae*

type B infection in Sweden was epiglottitis.^{88,443} In Sweden, the incidence of epiglottitis in children 14 years of age or younger in 1981 to 1983 was 10/100,000 per year. The annual incidence in Minnesota and Dallas County, Texas, in children 5 years of age or younger in 1982 to 1984 was 5.4 and 4.4 cases, respectively, per 100,000 per year.³¹⁵

In children in the United States in the prevaccine era, the peak occurrence of epiglottitis was during the third year of life, and 72% of all cases occurred in children 1 to 5 years of age.^{23,29,34,89,139,224} The disease occurred more commonly in boys than in girls; in eight studies with 611 cases, 58% of cases were in boys.^{23,29-31,34,89,139,224,309}

In specific geographic areas, marked differences in the yearly percentage of cases of epiglottitis occurred, but no intercity, national, or international cycles of illness were demonstrated.^{23,29,89,139,224,309} Seasonal prevalence varied by locality but was not marked. The greatest number of cases in three studies occurred in the winter and spring,^{34,224,309} whereas Baxter²⁹ observed more cases during the summer and in November, and Cohen and Chai⁸⁹ found no seasonal pattern.

Epiglottitis is a disease that occurs most commonly in temperate climates.^{143,226} In several U.S. military hospitals, a wide geographic variation in incidence was noted; no cases were found among 4625 admissions at Gorgas Hospital in Panama, whereas 1/600 admissions to Elmendorf Hospital in Alaska were for epiglottitis.²³ In the past, acute epiglottitis had not been reported in either Taiwan or Hong Kong.²²⁰

Epiglottitis also occurs in adults but less commonly than in children.^{151,293,428,446} Annual rates in Rhode Island, Denmark, Finland, and northern California were 1.0, 0.9, 0.2, and 1.8/100,000, respectively. In both Ireland and Israel, rates of reported epiglottitis in adults appear to be increasing.^{32,183} Whether these increases are true increases or are the result of increased awareness is not apparent.

In the present *H. influenzae* type B conjugate vaccine era, the incidence of epiglottitis has fallen dramatically in all countries employing routine immunization, as has the incidence of all invasive disease caused by *H. influenzae*.^{*} In northern Finland, the incidence in children 4 years of age or younger fell from 7.6/100,000 before 1988 to 0/100,000 after 1988.⁶ In Sweden, in the 10-year period from 1986 to 1996, the rate of epiglottitis in children younger than 14 years fell from 8.2/100,000 to less than 1/100,000.¹⁶⁰ At the Children's Hospital of Philadelphia, the average annual incidence of epiglottitis declined from 10.9/10,000 admissions before 1990 to 1.8/10,000 admissions from 1990 through 1992.¹⁷⁴ In this study, investigators also noted that the median age of patients increased from 35.5 months before 1990 to 80.5 months in the post-1989 period.

It should be noted that sporadic cases of epiglottitis mostly caused by non-*H. influenzae* type B bacteria continue to occur in the United States.³⁹⁵ In 2006, 377 cases were reported including 369 cases in children.

In 2006, an increase in incidence of invasive *H. influenzae* type B disease, including acute epiglottitis, was reported in England.³⁰⁰ Many of the cases occurred in children who had received *H. influenzae* type B conjugate vaccine at 2, 3, and 4 months of age but not a booster dose in the second year of life. This resurgence of invasive *H. influenzae* type B disease led to the implementation of a booster dose at 12 months of age, which helped to control the burden of invasive *H. influenzae* type B in all age groups.⁹¹

PATHOLOGY AND PATHOGENESIS OF CROUP

Laryngoscopic studies in acute laryngotracheitis reveal redness and swelling of the lateral walls of the trachea, just below the vocal cords.^{110,109,426} Because the subglottic trachea is surrounded by a firm cartilaginous ring, the inflammatory swelling can occur only by encroaching on the patency of the airway; the subglottic space often is reduced to a slit 1 to 2 mm wide. As the disease progresses, the tracheal lumen becomes obstructed further by a fibrinous exudate, and its surface is covered by pseudomembranes composed of the exudative material. The vocal cords frequently are swollen, and their mobility is impaired.

Histologic study of postmortem material from the larynx and trachea reveals marked edema and cellular infiltration in the lamina propria,

*References 6, 59, 140, 154, 174, 181, 276, 300, 303, 341, 448, 460, 479.

submucosa, and adventitia. The cellular infiltrate includes histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes.^{54,56,312,334,357} The cotton rat model of laryngotracheitis caused by human parainfluenza virus type 3 reveals pathologic findings similar to those noted in human postmortem studies.³³⁵ This model also indicates the time course of events. Early in the course of an infection (first 2 to 4 days), moderate mucosal and submucosal inflammatory infiltrates were noted in the subglottic and proximal tracheal regions. The infiltrates initially contained lymphocytes and neutrophils, and subsequently a mononuclear infiltrate with lymphocytes and macrophages in the submucosa was noted. Cell injury was most marked on days 6 to 8 after infection. The ciliated epithelial cells were blunted, with loss of cilia in large patches. By 12 days after infection, the region reverted to a nearly normal appearance.

The older literature indicates that classic laryngotracheobronchitis and the same disease with pneumonia represent extension of disease from the trachea to the bronchi and alveoli. The progressive obstructive disease with exudate and pseudomembrane obstruction at the bronchial and bronchiolar levels usually is the result of secondary bacterial involvement. In bacterial croup, the tracheal wall is infiltrated with inflammatory cells, and ulceration, pseudomembranes, and microabscess formation occur.* In addition to the findings in laryngotracheitis of viral origin, thick pus is present within the lumen of the trachea and lower air passages.^{193,233,277,297}

Spasmodic croup is an enigma because it occurs in association with respiratory viral infections similar to those that cause more severe laryngotracheitis. Using direct laryngoscopy, Davison¹¹⁰ noted that the subglottic tissues in spasmodic croup showed noninflammatory edema.

Although the eventual site of clinically important pathologic change in laryngotracheitis is within the larynx and trachea, the initial acquisition of infection is similar to that of other respiratory viral infections and occurs within the upper air passages, including the nasal and pharyngeal epithelial surfaces. After acquisition of virus, infection of the cells of the local respiratory epithelium develops and spreads locally to involve the larynx and trachea. The initial symptoms of nasal stuffiness and throat irritation reflect the primary sites of involvement. Studies in organ culture systems and in the cotton rat model have shown that several respiratory viruses inhibit tracheal ciliary function and eventually lead to marked destruction of the epithelium and evidence of viral infection in the lamina propria.^{246,335,353} In uncomplicated croup, failure of gas exchange within the lung, in addition to hypoxia resulting from subglottic tracheal obstruction, may occur.^{323,432}

Parainfluenza virus types 1, 2, and 3 all are significant causes of respiratory infections in children (see Chapter 179). Infection with parainfluenza virus type 3 occurs in most infants, whereas infections with types 1 and 2 generally occur more frequently in older children. Only a third of children have antibodies against these two viral types by the time they reach 4 years of age.

Because parainfluenza viral infections are common occurrences in young children, and because only a few get croup, host factors probably are important in the pathogenesis. In contrast to the numerous studies of the pathogenesis of bronchiolitis and respiratory syncytial virus infection, few similar studies relating to parainfluenza viruses and croup have been reported.^{84,382,485}

These pathologic data suggest that the findings in laryngotracheitis are directly virus related (parainfluenza virus types 1, 2, and 3 and influenza virus types A and B) because of the direct cytopathic effect of a virus, are related to the concomitant host response, or perhaps both.^{84,382,485} In the cotton rat model, the use of topical steroid therapy led to a significant reduction in the degree of inflammatory infiltrates and cell injury, which suggests that the host response contributes to the pathologic findings.³³⁵ Schaap-Nutt and associates³⁷⁷ described the replication kinetics and cytokine secretion of the parainfluenza viruses in human tracheobronchial airway epithelium. They found serotype-specific differences of the innate immune response, suggesting that parainfluenza type 1 is able to remain undetectable for several days after infection compared to parainfluenza type 2 and 3. Parainfluenza

2 inhibits the early immune response to a lesser extent than the other serotypes, and parainfluenza 3 triggers a steady increase of the basolaterally secreted cytokines. These findings are consistent with both the epidemiology and clinical findings in croup. The pathogenesis of laryngotracheobronchitis and laryngotracheobronchopneumonitis is similar to that described previously but with the extension of infection to the lower respiratory tract and usually the occurrence of secondary bacterial infection.

Many studies suggest that allergic factors play a role in recurrent croup.^{68,195,326,449,468-470,477,483} Welliver and associates⁴⁶⁹ found that children with croup caused by parainfluenza viral infections had titers of IgE-specific antibody in their nasopharyngeal secretions that were 3.6-fold higher than titers of similarly infected children with only upper respiratory tract infections. The children with croup had a cell-mediated immune response to parainfluenza virus that was 1.6-fold greater than that of the children with only upper respiratory tract infections.

In a subsequent review, investigators noted that an atopic disposition might be associated with the development of croup.⁴⁶⁸ Children with croup caused by a parainfluenza virus had specific IgE antibodies and released histamine into the airway more frequently than did control patients with parainfluenza viral upper respiratory tract infections. They also noted that children with recurrent croup had several atopic features, such as positive skin tests to environmental allergens, and were more likely to develop asthma when they grew older. Also, some children with a history of recurrent croup develop stridor with histamine challenge. Rennie and associates³⁵⁵ found that children with C/T genotype of the CD14 G-1359T SNP were more likely to have a history of croup, and children with genotype homozygous C/C had low prevalence of croup in this study. This suggests that CD14 polymorphisms may influence the innate response to viral infections associated with croup.

The above-mentioned studies by Welliver and associates^{468,469} and other reports make it easy to accept a role of atopy in recurrent croup. What is difficult to explain, however, is why many apparently primary infections result in only spasmodic croup. As one of us (JDC) suggested previously, initial sensitization may be parainfluenza virus group-specific and not type-specific.³⁷ This idea suggests that early infection (primary infection) with parainfluenza virus type 3 would set the stage for spasmodic croup with parainfluenza viral types 1 and 2. The primary infection itself could have been mild owing to transplacentally acquired antibody.

ANATOMY AND PATHOPHYSIOLOGY OF SUPRAGLOTTITIS

The thin, elastic, leaflike epiglottic cartilage is attached to the anterior surface of the thyroid cartilage by the thyroepiglottic ligament (Fig. 18.1). The hyoepiglottic ligament also provides support and anchors the epiglottis to the hyoid bone. The superior aspect of the epiglottis arches slightly posteriorly. Stratified squamous epithelium covers the anterior surface of the epiglottis and the superior third of the posterior portion; respiratory epithelium covers the remaining posterior surface. The stratified squamous epithelium is loosely adherent and creates a large potential space for the accumulation of inflammatory cells and edema fluid.

The arytenoepiglottic folds arise from the epiglottis and terminate posteriorly near the paired arytenoid cartilages. These structures commonly are involved in the supraglottic infection and occasionally are the site of serious disease without epiglottitis per se.²⁹ Immediately anterior to the epiglottis are the valleculae epiglotticae, where saliva pools before deglutition.

Supraglottic cellulitis with marked edema involving the epiglottis, arytenoepiglottic folds, ventricular bands, and arytenoids is the hallmark of this illness. As the edema increases, the epiglottis curls posteriorly and inferiorly. Inspiration tends to draw the inflamed supraglottic ring into the laryngeal inlet, whereas expiration is unopposed.³⁹⁰ This “ball-valve” mechanism is thought to produce slight hypoxia without hypercapnia.³⁷⁹ Diffuse infiltration with polymorphonuclear leukocytes, hemorrhage, edema, and fibrin deposition can be seen microscopically; this infiltration can progress to microabscesses, with *H. influenzae* type B occasionally seen in the tissue.^{226,364} Frank abscess formation has been

*References 7, 77, 78, 81, 82, 92, 114, 123, 126, 131, 137, 173, 193, 201, 227, 233, 277–279, 321, 327, 411, 424.

FIG. 18.1 Anatomic relationships of the supraglottic larynx. Posterior view (left) and sagittal view (right).

documented in adults.^{32,274,288,360,374,416,464,475} Infection of the supraglottic larynx may spread inferiorly to involve the paraglottic space,¹⁸⁹ but as a rule, neither upward extension into the laryngeal lymphatics nor downward extension into the subglottic region occurs.^{31,226}

Infection of the supraglottic structures probably arises from direct invasion by *H. influenzae* type B, with subsequent development of bacteremia. The bacteremia appears to be relatively short in duration and of low concentration, as suggested by several observations: (1) the serum concentration of the capsular polysaccharide is directly proportional to the concentration and duration of bacteremia,³⁸⁰ (2) children with epiglottitis have less *H. influenzae* type B capsular polysaccharide in their sera than do patients with meningitis,⁴⁶² and (3) the density of *H. influenzae* type B in blood is significantly lower in patients with epiglottitis than in patients with meningitis.^{259,376,420} In 23 patients with epiglottitis, the geometric mean number of organisms was 123 colony-forming units (CFUs)/mL, whereas the geometric mean number in 43 patients with meningitis was 2203 CFU/mL ($P < .001$).²⁵⁹

What predisposes the epiglottis to infection is unknown. Possibly, mild trauma to the epiglottis occurs during food intake. This trauma could result in damage to the mucosal surface, which, in turn, could allow the invasion of organisms that already were present in the upper respiratory tract. Also possible is that a viral infection damages the mucosal surface and thus predisposes the patient to secondary bacterial infection.

Acute-phase sera in most children with epiglottitis lack specific *H. influenzae* type B bactericidal and hemagglutinating antibody. Seroconversion regularly occurs after infection.^{30,289}

Conflicting evidence exists relating to a possible genetic difference between patients with *H. influenzae* type B epiglottitis and other individuals.^{8,176,433,475} Whisnant and associates⁴⁷⁵ surveyed human leukocyte antigens (HLAs) and erythrocytic antigens among 30 children with epiglottitis and 20 patients with meningitis. HLA-A11 was found in 3% and 17% of the patients with epiglottitis and meningitis, respectively ($P < .01$). HLA-B5 occurred in 3% and 13% of patients with meningitis and epiglottitis, respectively ($P < .05$), whereas HLA-B40 occurred more often (23% vs. 10%) in patients with meningitis than in those with epiglottitis ($P < .05$). Moreover, the frequency of HLA-A28 and HLA-B17 was higher among the patients with epiglottitis than in uninfected control subjects.⁴⁷⁵ However, the results of another study did not confirm these observations.¹⁷⁶

The distribution and frequency of MNS erythrocyte antigens in patients with epiglottitis may differ from those observed in others. For example, the NNSS genotype occurred in 6.4% of patients with epiglottitis and in 0.5% of healthy control subjects ($P < .0002$),⁴⁷³ but this difference was not confirmed.¹⁷⁶ However, the results of two studies suggest that the MNS genotype occurs less often in patients with *H. influenzae* type

B meningitis than in patients with epiglottitis.^{176,475} In one study, white children with *H. influenzae* type B meningitis lacked G2m(n), an allotype antigen of immunoglobulin (Ig) G2 subclass heavy chains, more frequently than did control subjects.⁸ In another study in a white population in Finland, however, this difference was not noted.⁴²⁹ The frequency of the Km(1) immunoglobulin allotype in children with epiglottitis did not differ significantly from the prevalence of that marker in blacks or whites. However, in blacks with *H. influenzae* type B meningitis, the Km(1) marker occurred less frequently in patients than in control subjects.¹⁷⁶ The identification of one outer membrane protein subtype of *H. influenzae* type B that was associated relatively infrequently with epiglottitis suggests that isotype-specific differences in the propensity of *H. influenzae* type B to cause epiglottitis may exist.⁴³⁰

CLINICAL PRESENTATION

Acute Laryngitis

Table 18.3 summarizes clinical characteristics of laryngitis. Laryngitis is mainly a disease of older children, adolescents, and adults that is disturbing but self-limited. The specific clinical manifestation is hoarseness. Other symptoms depend on the causative infectious agent. Adenoviruses and influenza viruses cause the most severe instances of laryngitis. With these viruses, fever usually occurs, and sore throat, headache, muscle aches and pains, and prostration are common symptoms. In contrast, patients with laryngitis resulting from rhinoviral, parainfluenza viral, or respiratory syncytial viral infections have minimal or no fever and few systemic complaints. They usually have pronounced nasal symptoms (coryza and stuffiness), however. Occasionally hoarseness may persist, which may be a result of secondary bacterial infection of the upper respiratory tract.

Acute Laryngotracheitis

Although the clinical spectrum of acute laryngotracheitis varies considerably, its manifestations usually are significantly different from the manifestations of the other acute diseases with obstruction in the region of the larynx (see Table 18.3). Onset of illness usually is not alarming and suggests the onset of a cold. Initial symptoms are nasal complaints and include dryness, irritation, and coryza. Ordinary cough and the complaint of sore throat occur frequently. Fever is a usual occurrence within the first 24 hours, which is not true of the common cold. After a period as short as a few hours, but usually after 12 to 48 hours, upper airway obstructive signs and symptoms are seen. The cough first becomes “croupy” (sounding like a barking seal), and then evidence of respiratory stridor (difficulty associated with inspiration) gradually increases. Examination at this time reveals a child with a hoarse voice, coryza, a normal or minimally inflamed pharynx, and a slightly increased

TABLE 18.3 Differential Diagnosis of Acute Obstruction in the Region of the Larynx

Laryngotracheobronchitis and Laryngotracheobronchopneumonitis (Including Bacterial Tracheitis)						
Category	Acute Epiglottitis	Laryngeal Diphtheria	Laryngitis	Acute Laryngotracheitis	Spasmodic Croup	Foreign Body
Common age of occurrence	1–8 y	All ages	Older children and adults	3 mo to 3 y	3 mo to 3 y	All ages
Past and family history	Not contributory	No or inadequate immunization	Not contributory	Family history of croup	May be family history of croup	Occasional history of ingestion
Prodrome	Occasionally coryza	Usually pharyngitis	Usually stuffy nose or coryza	Usually coryza	Minimal coryza	None
Onset (time to full-blown disease)	Rapid; 4–12 h	Slowly for 2- to 3-day period	Variable; 12 hr to 4 days	Moderate but variable; 12–48 h	Sudden; always at night	Usually sudden
Symptoms on presentation						
Fever	Yes; usually 39.5°C (103°F)	Yes; usually 37.8°C to 38.5°C (100°F to 101°F)	Yes; 37.8°C to 39.4°C (100°F to 103°F) with adenoviral and influenza viral infections; usually minimal with other viruses	Yes; variable, 37.8°C to 40.5°C (100°F to 105°F)	No	No, unless secondary infection
Hoarseness and barking cough	No	Yes	Yes	Yes	Yes	Usually no
Dysphagia	Yes; usually severe	Usually yes	No	No	No	Frequently yes
Inspiratory stridor	Yes; moderate to severe	Yes; minimal to severe	No	Yes; minimal to severe	Yes; moderate	Variable
Toxic appearance	Severe	Usually no	No	Usually minimal	No	No
				Usually moderate; may be severe		No
						Occasional history; perhaps previous attack
						Occasionally cutaneous allergic manifestations
						Rapid
						Acute Angioneurotic Edema

Signs on presentation

Oral cavity	Pharyngitis and excessive salivation	Membranous pharyngitis	Normal or mild to moderate pharyngitis	Usually minimal pharyngitis	Normal	Normal	Pale appearance
Epiglottitis	Cherry-red and swollen	Usually normal; may contain membrane	Normal	Normal	Normal	Normal	Swollen and pale
Radiographs	Swollen epiglottitis on lateral film	Not useful	Not useful	Subglottic narrowing on PA film	Subglottic narrowing on PA film; irregular soft tissue densities within trachea on lateral film	Not useful	Swollen epiglottitis on lateral film
Laboratory							
Leukocyte count	Usually markedly elevated with increased percentage of band forms	Usually elevated with increased percentage of band forms	Usually normal	Mildly elevated with >70% polymorphonuclear cells	Variable; usually mildly elevated with 70% polymorphonuclear cells; may be increased band count	Normal	Normal; sometimes eosinophilia
Bacteriology	Throat and blood cultures yield <i>Haemophilus influenzae</i> type b	Smear and culture from membrane reveal organism	Usually normal flora in throat; occasionally <i>Streptococcus pyogenes</i> in throat	Only important if secondary infection suspected	Normal throat flora; tracheal culture often yields <i>S. pyogenes</i> , <i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , or <i>H. influenzae</i>	Normal flora	Normal flora
Clinical course	Rapidly progressive; cardiorespiratory arrest occurs within hours if not treated	Slowly progressive obstruction of airway	Hoarseness persists at a constant degree about 4–7 days; occasionally persists 2–3 wk	Variable speed of progression of obstruction; usually does not require surgical intervention	Degree of obstruction usually severe; persists 7–14 days; frequently requires surgical intervention	Symptoms of short duration with treatment; repeated attacks common	Variable; sometimes leads to rapid asphyxia without therapy

Data from references 109, 110, 114, 131, 144, 159, 193, 227, 277, 278, 302, 434.

respiratory rate with a prolonged inspiratory phase. Temperature nearly always is between 37.8°C and 40.5°C (100°F and 105°F).

The speed of progression and final degree of upper airway obstruction vary. Some children have hoarseness and barking cough but no other evidence of obstruction; in these cases, the symptoms last approximately 3 to 7 days, with a gradual return to normal. In other cases, the obstruction is progressive and leads to severe respiratory distress with suprasternal and infraclavicular and sternal retractions, cyanosis of varying degrees, and apprehension. With hypoxia, the cardiac rate increases and the child becomes restless. Without intervention, asphyxial death occurs rapidly in some children. In others, the problem of hypoxia is more prolonged, and respiratory fatigue may lead to the patient's demise. The duration of illness in a severely affected child, regardless of therapy, is rarely less than 7 days and frequently is 14 days.

Laboratory study in acute laryngotracheitis is of only minimal value. The white blood cell count frequently is greater than 10,000 cells/mm³, and polymorphonuclear cells predominate.^{79,325} Very high white blood cell counts (>20,000/mm³) with numerous band-form neutrophils should suggest bacterial superinfection or the possibility of acute epiglottitis. The posteroanterior chest radiograph reveals the subglottic narrowing (steeple sign), and a lateral neck radiograph indicates the size of the epiglottis.

Acute Laryngotracheobronchitis and Laryngotracheobronchopneumonitis (Bacterial Tracheitis)

Laryngotracheobronchitis and laryngotracheobronchopneumonitis are far less common occurrences than laryngotracheitis and spasmodic croup; however, these illnesses occur more commonly than generally realized.* These entities may be considered an extension of acute laryngotracheitis, as numerous descriptions in the literature suggest.[†] The severity of the illness is due to secondary bacterial infection. Initial signs and symptoms are similar to those of laryngotracheitis (see Table 18.3). An afflicted child usually has mild to moderately severe illness for 2 to 7 days and then suddenly becomes markedly worse. Occasionally upper and lower airway obstructions seem to occur simultaneously. In many children, the distress from tracheal obstruction is of such magnitude that the signs and symptoms of lower respiratory tract involvement go unnoticed. Signs and symptoms associated with extension of disease to the bronchi, bronchioles, and lung substance include rales, air trapping, wheezing, and a further increase in the respiratory rate. Obstruction in these illnesses usually is of such a degree that either intubation or tracheostomy is necessary.

Several instances of laryngotracheobronchopneumonitis with toxic shock syndrome have been observed.^{58,77,327,412,424} Generally children with these staphylococcal infections initially have the onset of croup, then the more severe manifestations of bacterial tracheitis develop, and finally the exanthem and other manifestations of toxic shock syndrome develop. An infant with tracheitis and supraglottitis caused by *M. catarrhalis* has been described.⁷ Other findings in laryngotracheobronchitis and laryngotracheobronchopneumonitis are presented in Table 18.3.

Spasmodic Croup

In recent years, the clinical entity of spasmodic croup has been incorporated by many physicians into the overall diagnosis of croup. Although distinguishing mild cases of laryngotracheitis from spasmodic croup is difficult at the onset in some instances, the delineation of the two entities is important from prognostic and therapeutic perspectives (see Table 18.3).

Spasmodic croup occurs in children 3 months to 3 years of age. The onset always is at night, and the characteristic presentation occurs in a child who previously was thought to be well or to have had a mild cold with coryza as the only symptom. The child awakens at night with sudden dyspnea, croupy cough, and inspiratory stridor but no fever. The symptoms apparently are the result of sudden subglottic edema; relief is achieved easily by general reassurance and administration of

moist air. The occurrence of spasmodic croup tends to run in families, with repeated attacks occurring in some children. After one attack, the child is likely to have another attack the same evening and on three or four successive evenings. These attacks can be prevented by employing mild sedation at bedtime and ensuring that the bedroom air is adequately humidified.

Supraglottitis

The classic onset of epiglottitis in children is abrupt, and progression of disease is rapid; careful history on occasion reveals the occurrence of a trivial antecedent upper respiratory tract infection.* The total duration of illness before hospitalization usually is less than 24 hours and occasionally is as short as 2 hours. In one study in which 142 medical records of children with epiglottitis were reviewed, the duration of illness before tracheotomy was performed was found to be 12 hours or less in 73% and more than 24 hours in only four patients.⁸⁹

The most common presentation of acute epiglottitis in children includes the sudden onset of fever, severe sore throat, dysphagia, and drooling. Airway obstruction always occurs and is rapidly progressive. It is manifested by distress on inspiration, a choking sensation, irritability, restlessness, and anxiety. The speech is muffled or thick sounding, but hoarseness usually does not occur. Aphonia was described in a 4-day-old infant with epiglottitis and concomitant MRSA skin and urinary tract infection.³²⁸ The child usually insists on sitting up in a characteristic posture with the arms back, the trunk leaning forward, the neck hyperextended, and the chin pushed forward. This posture increases the diameter of the obstructed airway.

In contrast to acute laryngotracheitis, in which marked inspiratory stridor occurs, the degree of observed stridor in epiglottitis often is not severe. This apparent lack of respiratory distress often leads the unwary physician to underestimate the severity of the child's illness. With progression, the air exchange becomes progressively worse, and hypoxia, hypercapnia, and acidosis develop. These developments cause increased irritability, restlessness, and disorientation, and if an artificial airway is not established, the child will experience sudden cardiorespiratory arrest.

Fever occurs in virtually all children; most temperatures are between 38.8°C and 40.0°C (101.8°F and 104°F). Blood leukocyte counts almost always are elevated; the mean total count was approximately 20,000 cells/mm³ in five studies.^{6,34,89,224,466} The differential cell count reveals an increased percentage of neutrophils and band forms; most patients have absolute band counts of more than 500 cells/mm³.

The clinical picture of epiglottitis in adults is more indolent than that in children.^{32,188,413,487} Berger and associates³⁴ reviewed 118 cases of acute epiglottitis seen between 1986 and 2000. Of these patients, 33% were admitted to the hospital within 1 day of the onset of symptoms, and 77% were admitted within 3 days of onset. Symptoms on admission were as follows: sore throat, 85%; odynophagia, 83%; temperature elevation, 38%; respiratory difficulties, 34%; muffled voice, 25%; and drooling, 7%. In two other studies, an average of 1 to 3 days elapsed before medical aid was sought. The mean temperature was 38.2°C (100.7°F), and some patients were afebrile; the temperature range was 36.6°C to 40.0°C (98.0°F to 104°F). Blood leukocyte counts averaged 17,000/mm³ (range, 8000 to 32,000/mm³).^{188,413} Sore throat and dysphagia were universal occurrences. Zwahlen and Regamy⁴⁸⁷ reviewed the clinical features of 100 reported adult cases of epiglottitis. Of these patients, 78% had dyspnea, 49% had dysphonia, 41% had cyanosis, and 38% had stridor. Forty-six percent had edema of the neck. A precordial purring or fluttering sensation was described by one adult patient.³⁸¹ In three cases in adults, Ehara¹³² noted on physical examination that all had tenderness of the anterior neck over the hyoid bone.

DIFFERENTIAL DIAGNOSIS

The therapeutic approaches to the various acute obstructions in the region of the larynx vary markedly. Establishing a correct diagnosis is essential and frequently lifesaving. Table 18.3 lists the differential points

*References 35, 78, 92, 114, 123, 126, 131, 137, 173, 185, 193, 201, 227, 233, 277, 278, 297, 305, 319, 424, 478.

†References 28, 54, 56, 108, 109, 138, 165, 208, 233, 299, 334, 348, 349, 356, 357.

*References 23, 26, 31, 34, 50, 57, 89, 139, 188, 224, 225, 273, 282, 289, 290, 309, 333, 347, 401, 455, 474.

of eight conditions with symptoms and signs of acute upper airway obstruction.

The most frequent serious differential diagnostic problem is the recognition of acute epiglottitis and its separation from the less fulminant laryngotracheitis. In epiglottitis (a rare disease in children today because of universal immunization with *H. influenzae* type B conjugate vaccines), the important differential points are lack of a croupy cough; the presence of a swollen, cherry-red epiglottis; the sitting posture of the child with the chin pushed forward and a reluctance or refusal to lie down; and the relatively greater apprehension and anxiety of the patient than the degree of chest retraction suggests. In contrast, a child with acute laryngotracheitis has a normal epiglottis on examination, always has a typical barking cough, is comfortable in a supine position, and frequently appears to have only minimal apprehension, despite retractions in which the sternum appears to be indenting 2 inches or more.

Early in the course of epiglottitis, the diagnosis can be confirmed only by the observation of the epiglottis, which can be done without difficulty.²⁴⁹ Later in the disease, the posture of the child and the history of rapidly progressing disease render the differential from laryngotracheitis readily apparent, so examination of the epiglottis directly (a dangerous procedure if the child is forced to lie down) or indirectly by a lateral neck radiograph rarely is indicated and usually is contraindicated. A study in adults found that bedside sonography could be used as a diagnostic tool for acute epiglottitis in the emergency department.²⁴⁷

Laryngotracheobronchitis and laryngotracheobronchopneumonitis can be recognized by signs of lower respiratory involvement (rales, air trapping, wheezing, and pulmonary infiltrates on the radiograph). Bacterial disease should be suspected in laryngotracheobronchitis and laryngotracheobronchopneumonitis and when symptoms and signs become worse in laryngotracheitis. A lateral radiograph can be useful in the evaluation because it may reveal soft tissue densities within the trachea. Lateral neck and chest radiographs are regarded by many physicians as definitive tests to determine whether to rule out epiglottitis and laryngotracheitis. In a careful study by Stankiewicz and Bowes,⁴¹⁵ the sensitivity and specificity of both radiographs were low, however.

Although a rare occurrence today, laryngeal diphtheria always should be considered and ruled out in croup. Recently Hsia and associates²⁰⁵ noted a child with Guillain-Barré syndrome who initially presented with a crouplike cough.

Spasmodic croup is rarely confused with acute laryngotracheitis, but a perusal of the literature indicates that the two entities most commonly are considered laryngotracheitis, which is unfortunate because prognostic considerations for the two entities are different. Spasmodic croup always is of sudden onset at night, occurs without fever, and is relieved by simple therapeutic modalities.

The possibility of a foreign body and angioneurotic edema always must be considered in upper airway obstructive disease. Differential points are presented in Table 18.3. Rarely acute upper airway obstruction occurs in adolescents as a result of psychogenic and emotional factors.^{162,241,378}

There are many causes of recurrent croup in infants and children, and many of these cases should have operative evaluation by an otolaryngology service.^{93,113,128,178,350} Diagnostic possibilities include subglottic stenosis, laryngomalacia, bronchomalacia, tracheomalacia, vascular compression of distal trachea, stenosis of left main bronchus, subglottic cyst, tracheoesophageal fistula, unilateral vocal cord immobility, tracheal bronchus, and esophagitis and gastroesophageal reflux disease.

SPECIFIC DIAGNOSIS IN CROUP SYNDROMES

The epidemiologic history frequently is an important factor in establishing a specific diagnosis. Obtaining bacterial culture specimens from the throat, laryngeal region, and blood is helpful in diagnosing epiglottitis and important in identifying laryngotracheitis, laryngotracheobronchitis, and laryngotracheobronchopneumonitis when secondary infection is suspected. The white blood cell count should be obtained because it can be helpful when secondary bacterial infection is considered.

A specific etiologic diagnosis can be made by the isolation of virus or its identification by a direct antigen test from a nasopharyngeal specimen. The diagnostic virologic facilities of many medical centers

enable rapid identification of parainfluenza viruses, respiratory syncytial viruses, adenoviruses, most rhinoviruses, and influenza viruses to be established.

SPECIFIC DIAGNOSIS IN SUPRAGLOTTITIS

The clinical picture of sore throat, dysphagia, drooling, anxiety, and inspiratory distress without significant stridor and the characteristic sitting position should suggest the presumptive diagnosis in most cases. The definitive anatomic diagnosis is made by visualization of the epiglottis, and the etiologic diagnosis is confirmed by culture of an organism from the blood or the surface of the epiglottis.

In the typical case, the epiglottis is fiery red and greatly swollen. In children, the epiglottis can be seen by simple depression of the tongue with a tongue blade. In older children and adults, indirect or direct laryngoscopy usually is necessary to confirm the diagnosis. On occasion, the obstruction is caused by swelling of the ventricular bands and the arytenoepiglottic folds so that the epiglottis may appear relatively normal.

Major controversy exists concerning the safety of using a tongue depressor to examine a child with suspected epiglottitis because sudden cardiorespiratory arrest has been noted to occur. However, most instances of cardiorespiratory arrest occurred after the child was forced into a supine position rather than because of the examination itself.⁸⁰ In many instances, patients with presumptive epiglottitis can be examined while they are in an upright position by using a tongue blade or indirect laryngoscopy.

Case management should be individualized. In the child with moderate or advanced disease, the clinical diagnosis should be apparent without having to do an intraoral examination. In this situation, intraoral examination should not be performed, but the child should be prepared for the establishment of an airway. This preparation should be rapid but controlled so that intubation can be performed in an operating room.

The diagnosis of epiglottitis can be established by the classic appearance on a lateral neck radiograph (Fig. 18.2).^{351,466} However radiographic procedures could lead to a delay in providing the necessary definitive therapy.^{89,226,304} The use of the lateral neck radiograph should be reserved

FIG. 18.2 A lateral neck radiograph from a child with acute epiglottitis shows the swollen epiglottis (thumb sign) encroaching on the airway. (Courtesy Dr. Ines Boechat.)

for subacute cases in which the specific diagnosis after completion of a clinical examination is not clear.

The lateral film of the neck, delineating the soft tissues and taken with the patient upright, gives the best view of the upper airway anatomy (see Fig. 18.2). The hypopharynx is dilated; normal cervical lordosis may be replaced by a straight or kyphotic contour. The valleculae are narrowed and may be obliterated. A thickened mass of tissue stretching from the valleculae to the arytenoids emphasizes the appropriateness of the term *supraglottitis*. In adults with epiglottitis, the widths of the epiglottis and arytenoepiglottic folds uniformly exceed 8 and 7 mm, respectively.³⁸⁷

When performed, radiography of the neck in the anteroposterior projection usually reveals that tracheal narrowing is absent. However, some children with acute supraglottitis have localized subglottic narrowing indistinguishable from that found in acute laryngotracheitis.^{393,408}

All patients with suspected epiglottitis should have a blood culture, and a culture specimen should be obtained from the surface of the epiglottis when an artificial airway is established. Today, cultures are of increasing importance because of the change in epidemiology of *H. influenzae* type B infection and the resulting increased likelihood that a different organism may be causing the illness. A white blood cell count with a differential also may provide useful information. In children who have received antimicrobial treatment before cultures were obtained, performing a direct antigen test for *H. influenzae* type B on the blood and urine is worthwhile.

TREATMENT OF CROUP

During the past 70 years, the treatment of croup has created considerable controversy: tracheostomy versus no tracheostomy, intubation versus tracheostomy, warm versus cold humidification, antibiotics versus no antibiotics, corticosteroids versus no corticosteroids, sedation versus no sedation, and racemic epinephrine therapy versus mist therapy alone. Few of these controversies have been resolved scientifically, but the passage of time has lessened the importance of some of the discrepant opinions.

Of most importance in the evaluation of therapeutic modalities and the specific approach to therapy in croup is making an accurate differential diagnosis. A look at the most important controversy (the use of steroids) indicates that in most instances cases of spasmodic croup, in which a favorable outcome invariably can be expected, were not separated clinically from cases of laryngotracheitis, in which the outcome is less predictable.

Acute Laryngotracheitis and Spasmodic Croup

In managing acute laryngotracheitis and spasmodic croup, each case must be treated individually; one child may need minimal therapy, whereas another may require consideration of all modalities. In all children with acute laryngotracheitis, attention should be given to the anxiety and apprehension of the patient and parents. The parents should be reassured immediately, and it is important that the child is not separated from them. Physical examination should be done rapidly by one physician, and all but absolutely necessary procedures should be deferred.

In the past, mist therapy was the cornerstone of management of croup. In more recent years, the value of this therapy has been questioned.^{47,272,310,389} It had been one of our opinions (JDC), as expressed in previous editions of this book, that mist therapy in croup was useful. However, the results of a large randomized controlled trial³⁸⁹ and the extensive review by Moore and Little³¹⁰ indicate that mist treatment offers no benefit in treatment.

Oxygen should be administered to a child who is hypoxemic from respiratory distress. The studies of Newth and associates³²³ and Taussig and colleagues⁴³² indicate that mild hypoxemia occurs more commonly than is realized clinically. The drying effect of oxygen is counterproductive to the removal of tracheal exudate, so it should not be used routinely.

Since 1952, numerous communications in the English literature have described the use of corticosteroids in croup. Nine double-blind, controlled studies were conducted before 1989.^{129,130,217,249,258,271,406,422,425}

In 1964, Eden and Larkin¹³⁰ noted no difference between control and methylprednisolone therapy in a study of 50 children with acute croup. In 1967, Eden and colleagues¹²⁹ studied another 50 patients and could find no benefit from dexamethasone in contrast to a control preparation. Sussman and colleagues⁴²⁵ also could not show any benefit from dexamethasone therapy.

In contrast to these three studies, Skowron and coworkers⁴⁰⁶ noted a slight benefit regarding duration of stridor, retractions, fever, and days in the hospital in a group receiving dexamethasone. They suggested, however, that steroids not be used routinely for laryngotracheitis because the overall benefits were minimal and a potential risk exists in administration of steroids. In 1969, James²¹⁷ noted that dexamethasone-treated patients recovered from obstructive symptoms more quickly than did the control group. In another study involving 30 children, Leipzig and associates²⁷¹ concluded that dexamethasone in an adequate dose (0.3 mg/kg initially and repeated in 2 hours) given intramuscularly hastens the recovery from uncomplicated croup. This study and its predecessors have major inadequacies in design.^{81,445} In a study with 72 children, Koren and colleagues²⁴⁹ noted that dexamethasone did not offer any benefit to patients with laryngotracheitis but did decrease significantly the respiratory rate in children with spasmodic croup in contrast to placebo-treated control subjects. Although these findings were statistically significant, the benefits were not clinically significant.

Two additional modest studies of the use of dexamethasone in croup were published in 1988 and 1989, as was a meta-analysis of the evidence from the various randomized trials and a set of related editorials and a review.^{12,69,232,233,257,262,407,411,419} Kuusela and Vesikari²⁵⁸ concluded that dexamethasone was beneficial in acute spasmodic croup, and Super and associates⁴²² concluded that dexamethasone is beneficial in reducing the overall severity of moderate to severe acute laryngotracheitis during the first day of treatment.

The 1989 meta-analysis suggested that the use of steroids in children hospitalized with croup resulted in a significantly increased number with clinical improvement 12 hours and 24 hours after treatment and a reduced incidence of endotracheal intubation than occurred in the control subjects.²³² In this analysis, improvement at 12 hours was noted to be greater in the children who received higher initial doses of steroid (≥ 125 mg of cortisone) than in children who received lower doses.

In the early 1990s, nebulized steroids were evaluated in the treatment of croup, which led to another round of testimonials, controlled studies, and treatment articles supporting the efficacy of steroids.* Since the 1989 meta-analysis, more than 15 additional controlled steroid treatment trials have been performed, and another meta-analysis was published in 1999.¹⁵ Finally a large controlled trial of oral dexamethasone for mild croup was published in 2004, and a comprehensive meta-analysis was published in 2005.^{40,373} Also published more recently are many articles comparing doses, types, and methods of administration of steroids and a further round of commentaries.[†] On the basis of the three meta-analyses and the specific studies analyzed, most reviews on the management of croup recommend the routine use of steroids (administered orally, intramuscularly, or by nebulization) in the treatment of croup.[‡]

A past review of the data (by JDC) on the use of steroids in croup was concerning in that the specific clinical entity being treated was poorly defined, and no evidence indicated that steroids worked in any illness other than spasmodic croup.⁸¹ One recent meta-analysis on the effects of glucocorticoids in croup that includes 38 studies found that use of glucocorticoids improves symptoms as early as 6 hours and up to at least 12 hours after treatment. The study also showed significant improvement in the scores of croup severity, fewer return visits and/or (re)admissions, shorter length of stays, and reduced use of epinephrine.³⁷⁵

Of most concern today is that the risks of steroid use have not been evaluated and that, because of small sample sizes in all but two of the available studies, they cannot be evaluated by meta-analysis.

†References 39, 71, 84, 121, 122, 144, 145, 155, 161, 241, 285, 362, 375, 436.

‡References 10, 39, 41, 99, 111, 112, 144, 145, 171, 179, 210, 216, 217, 241–243, 245, 362, 365, 436.

Lower respiratory tract complications developed in three children receiving steroid treatment for croup. In one case, an adenoviral pneumonia worsened, and in the other cases bacterial tracheitis with pneumonia occurred. All three cases received corticosteroid treatment over the course of several days and not single-dose treatment. In the study of Super and colleagues,⁴²² two steroid-treated patients developed pneumonia during therapy; none of the control subjects developed pneumonia. In another trial in which 28 children received nebulized dexamethasone, two children with neutropenia developed bacterial tracheitis.²²³ Burton and associates⁶⁴ reported the occurrence of *Candida* laryngotracheitis as a complication of corticosteroid and antibiotic treatment in a child with croup, and Myers and colleagues³¹⁸ reported an infant who developed multiple pulmonary abscesses caused by *Legionella pneumophila* after receiving prolonged corticosteroid treatment of severe croup.

Today the standard of care for the initial treatment of laryngotracheitis and spasmodic croup is the use of corticosteroids administered orally, intramuscularly, or by nebulization.^{10,39,144} Recommended therapy is a single dose of intramuscular or oral dexamethasone. The limited use of nebulized budesonide also is effective. In the most definitive study, the treatment dose was dexamethasone 0.6 mg/kg given orally once.⁴⁰ In a subsequent review, Bjornson and Johnson³⁹ noted that the standard dose of dexamethasone is 0.6 mg/kg (oral or intramuscular); they suggested that oral is preferable because absorption is excellent, and peak serum concentrations are achieved as rapidly as with intramuscular administration. Recently Dobrovoljac and Geelhoed¹²⁰ reported on the effectiveness of a single 0.15 mg/kg dose of dexamethasone. They noted that this lower dose was as effective as the 0.6 mg/kg dose that they had previously used.

As noted earlier, we and others have observed bacterial and fungal infections as complications in children who have received multiple doses of steroids in croup. It is disturbing to note that in pediatric practice many children are receiving 3- to 5-day treatment courses rather than the recommended single-dose schedule. The data from the cotton rat model of human parainfluenza virus type 3 laryngotracheitis provide strong evidence supporting the limited use of steroids in croup.³³⁵ In this model, topical steroid therapy significantly reduced the degree of inflammatory infiltrates and cell damage. The steroid therapy increased the virus load but did not prolong virus shedding.

We believe the most dramatic evidence supporting the use of steroid therapy in laryngotracheitis and spasmodic croup is the marked decrease in the number of hospitalizations for croup in Ontario, which coincided with the 1992 recommendation by the Canadian Pediatrics Society to use dexamethasone for treatment.^{210,391} Steroids should not be used in laryngotracheobronchitis, laryngotracheobronchopneumonitis, or epiglottitis.

Because laryngotracheitis is a disease of viral etiology, it seems apparent that antibiotic therapy would not be indicated and consequently not employed. In an analysis of more than 200 hospitalized children with laryngotracheitis, it was noted that antibiotics had been administered to 85%.¹⁵⁸ A review of the records in many instances revealed that the physician had given antibiotic therapy because the possibility of epiglottitis had not been ruled out adequately. In several instances, the epiglottitis had been observed and thought to be reddened or questionably enlarged.

A second consideration with regard to antibiotic therapy in croup is that the most dramatic reduction in mortality rates coincides with the introduction and widespread use of antibiotics. In our opinion, many of the deaths attributed to croup in the preantibiotic era were caused by secondary bacterial infections. Although use of antibiotics contributed to the reduction in the number of deaths caused by croup, other factors may be important. At about the same time that antibiotics were introduced, disease caused by *S. pyogenes* decreased in incidence and severity. Reasons for the decreased frequency of streptococcal disease were not clear.

Most patients with laryngotracheitis today do not need antibiotic therapy. In severe cases in which bacterial sepsis cannot be ruled out, however, antibiotic therapy should be employed. The pathogens to consider include pneumococci, group A streptococci, *S. aureus*, and *H. influenzae*. In patients with laryngotracheitis in whom fever persists or

signs change, secondary infection should be considered. In these instances, appropriate culture specimens should be obtained before therapy is initiated (see the section on laryngotracheobronchitis for specific antibiotic therapy).

The use of nebulized racemic epinephrine, which was introduced by Jordan²²⁹ in 1966 and popularized by Jordan and other members of the Utah group,^{2,230} has been adopted widely throughout the United States and elsewhere.^{14,41,236,255,279,302,372,402} The usual method of nebulization of racemic epinephrine is by intermittent positive-pressure breathing. This form of therapy was associated with a marked reduction in tracheostomies in several series. In a review it was found that nebulized racemic epinephrine was no better than routine L-epinephrine and that intermittent positive-pressure breathing offered no advantage over simple nebulization.⁴¹

In 1973, Gardner and associates¹⁵⁹ performed the first double-blind controlled study in which racemic epinephrine was nebulized by a compressor without intermittent positive-pressure breathing. They found that saline-treated patients responded as well to therapy as did the racemic epinephrine recipients. In retrospect, this study can be criticized because the investigators failed to differentiate spasmodic croup from laryngotracheitis. In 1975, Taussig and associates⁴³² reported a small but carefully conducted study with intermittent positive-pressure breathing and racemic epinephrine in which they noted acute improvement in all cases, recurrence of symptoms in 2 hours, and no change in partial pressure of oxygen with clinical improvement; 24 to 36 hours after therapy, treated and untreated children were clinically similar. In another significant study that involved children hospitalized with severe croup without improvement after admission to a high-humidity mist room, Westley and colleagues⁴⁷³ showed that racemic epinephrine therapy caused definite short-term improvement in children compared with saline treatment. This study is particularly important because a parainfluenza viral etiology was documented in more than 65% of the study's subjects, and all cases were clearly laryngotracheitis and not spasmodic croup.

The following points can be made about the use of racemic epinephrine in the treatment of croup: (1) Many children with croup respond to moist air alone; (2) significant rebound occurs after racemic epinephrine therapy, so it frequently needs to be repeated many times; (3) in a hospitalized child with severe acute laryngotracheitis, racemic epinephrine should be used. Tracheotomy or endotracheal intubation can be prevented in some cases. The most important issue today regarding the use of racemic epinephrine is whether it can be used safely for outpatient therapy.^{94,234,344} In the past, most experts advised against the use of racemic epinephrine in the outpatient setting because of the known rebound that occurs. Some data suggest that with careful observation for a sufficient period (at least 2 hours) after administration, patients can be managed safely, and the number of hospitalizations can be decreased.^{94,234,344} In a small study, investigators found that the administration of a helium-oxygen mixture (heliox) resulted in improvement in children with croup similar to that with racemic epinephrine treatment.⁴⁶⁵ A systemic review found some evidence that suggested that heliox in steroid-treated patients provided short-term clinical improvement.³¹¹

The establishment of a mechanical airway seldom is necessary today in patients with laryngotracheitis. Traditionally tracheostomy was the preferred method when a mechanical airway was needed.^{18,153,486} When careful attention is given to tube size and other aspects of placement and maintenance, however, nasotracheal intubation compares favorably with tracheostomy.^{18,486} The management of a child with a mechanical airway requires trained pediatric intensive care physicians and the facilities of an adequately staffed intensive care unit.⁴⁶⁵

Five antiviral drugs have activity against viruses that cause laryngotracheitis.^{184,215,294,427,476} Amantadine and rimantadine are approved for use in treating influenza A viral infections, and ribavirin is active against parainfluenza viruses, influenza A and B viruses, and respiratory syncytial virus (see Chapters 178, 179, and 182). The neuraminidase inhibitors, zanamivir and oseltamivir, are active against influenza A and B types.^{70,95} At present, consideration of therapy for severe croup that occurs during documented epidemics caused by influenza A or B viruses would seem reasonable. Because of high levels of resistance of influenza

A strains to amantadine and rimantadine, treatment with the neuraminidase inhibitors is recommended.⁷⁰

Laryngotracheobronchitis and Laryngotracheobronchopneumonitis (Bacterial Tracheitis)

Generally all the treatment considerations discussed for laryngotracheitis except corticosteroids and racemic epinephrine by aerosol apply to laryngotracheobronchitis and laryngotracheobronchopneumonitis. Most important, however, because most patients have bacterial disease, antibiotics should be administered to all patients after appropriate culture specimens are obtained. Empiric therapy should be directed against *S. aureus*, *S. pyogenes*, *S. pneumoniae*, and *H. influenzae*. At present, initial treatment with vancomycin 40 mg/kg per day intravenously every 6 hours and a third-generation cephalosporin, such as cefotaxime 150 mg/kg per day every 6 hours intravenously, is reasonable. If methicillin-sensitive *S. aureus* is isolated, treatment should be changed to oxacillin 150 mg/kg per day every 6 hours intravenously or a similar agent.

Most children with advanced laryngotracheobronchitis or laryngotracheobronchopneumonitis need the placement of a mechanical airway. Whenever possible, this procedure should be done electively rather than as an emergency.

Laryngitis

Patients with laryngitis should rest their voices as much as possible. Increased fluid intake and perhaps the use of a vaporizer may help liquefy secretions and might provide symptomatic relief. Because group A streptococcal infection is a cause of laryngitis, culture should be performed. If it is positive, penicillin or a suitable alternative antimicrobial agent should be administered. In children and adolescents with prolonged hoarseness, sinusitis should be considered. Radiographs of the sinuses and a quantitative culture from the nose should be performed in search of a predominant abnormal bacterial flora. If either is positive, therapy with appropriate antibiotics is indicated. If laryngeal symptoms are persistent, the child should undergo laryngoscopic examination and other appropriate studies to exclude tumor, foreign body, and other chronic diseases.

TREATMENT OF SUPRAGLOTTITIS

The treatment of acute epiglottitis should be relatively simple in that it involves only two main aspects of therapy: an airway must be established, and an appropriate antimicrobial agent needs to be administered. However, in the past, the mortality rate from epiglottitis varied from 0% to 32%,^{89,188} a finding suggesting major differences in the implementation of treatment.

Most deaths occur in transit to the hospital or within the first few hours after arrival. Once the diagnosis is suspected, the patient should be attended constantly by individuals skilled in resuscitation with appropriate equipment for airway stabilization and ventilatory support. Delays of 2 or 3 hours have proved fatal; every effort should be made to reduce the time needed to secure a patient's airway and to initiate antibiotic therapy, before which unnecessary stress should be avoided. In most cases, radiographic confirmation should be omitted. Blood tests, extensive history taking, and delay in transport should be eliminated.

Medical centers and pediatric services that have planned protocols for the diagnostic investigation and treatment of patients with suspected acute epiglottitis generally have better morbidity and mortality statistics than do services that do not have such protocols in place. Pediatricians, radiologists, otolaryngologists, and anesthesiologists may contribute to the assessment and management of a case; defining roles and responsibilities of each service in advance minimizes confusion and renders the institution of care easier.

Securing the Airway

In general, the cornerstone of all management plans is the establishment of an airway in all children in whom the diagnosis of epiglottitis is made.⁸² In 1938, Sinclair⁴⁰⁰ recognized that tracheostomy was lifesaving. Berenberg and Kevy³² advocated hospitalization for all patients with epiglottitis but tracheostomy only "if necessary." However, Bass and

associates²³ presented a compelling argument for performing routine tracheostomy. Among 83 patients with documented epiglottitis, 11 of whom were adults, these authors noted that 16 (19%) had life-threatening obstruction when they were first seen. An additional 14 (17%) progressed to this point within 6 hours of admission; 9 of the 83 (11%) required emergency tracheostomy while they were hospitalized. Of these 9, 2 died and 1 suffered anoxic brain damage. All 9 were being monitored carefully, with bedside tracheostomy equipment available and trained personnel nearby. Six of the adults required tracheostomy for survival.²³ Margolis and colleagues²⁹⁰ noted that elective tracheostomy, performed at the time of diagnosis, eliminated fatalities in 15 consecutive patients. This observation was in contrast to four deaths in 20 patients observed until tracheostomy "was required."

A large body of literature attests to the safety and efficacy of nasotracheal intubation as a replacement for tracheostomy,* which has a complication rate of 50%.^{435,474} Biologically inert tubes, with their decreased risk for complicating subglottic stenosis,³⁹⁷ and the recollection that endotracheal tube insertion was a universal approach before tracheostomy³⁰⁴ was an accepted procedure led to the routine use of nasotracheal intubation in this disease. Nasotracheal intubation requires a shorter duration of airway maintenance: 32 patients with epiglottitis managed with tracheostomy had a mean duration of intubation of 7.5 days and a mean hospitalization of 8.8 days. In contrast, a nasotracheal tube was used for a mean of 38 hours with a 6.5-day hospitalization in five patients.³⁰⁴ Diaz and Lockhart¹¹⁹ managed 104 patients with nasotracheal intubation. The mean intubation time was 53 ± 14.9 hours; seven patients (6.8%) extubated themselves, and two required reintubation. Laryngeal edema occurred in three patients (2.9%) who had been intubated. In two patients, subglottic granulations required excision.

Our position, as well as that of Daum and Smith,¹⁰⁶ is that the argument for performing elective tracheostomy or, preferably, intubation in all children with supraglottitis is compelling, and the procedure should be performed immediately after the diagnosis is established. Whether this "stimulus-response" approach is necessary for adults with epiglottitis is controversial.^{21,150,188,337,390,399,413,477} MayoSmith and associates²⁹³ compared selected clinical features in adults with epiglottitis at the time of diagnosis who died or who received an artificial airway with those of adults who recovered without airway intervention. Few differences emerged. Patients who died or who were managed with airway intervention had respiratory distress and bacteremia more often than did those who recovered without airway intervention. Obviously the presence of bacteremia was not known on presentation. Moreover the mortality rate among all adults managed expectantly was 4.6%, a figure comparable to the mortality rate (6.1%) of children in a series reported before recommendations were made for routine securing of the airway at diagnosis.^{67,293} The preponderance of evidence until very recently has suggested that securing the airway in all adults with supraglottitis by nasotracheal intubation should reduce mortality rates.^{11,20–22,36,239,293} However, Frantz and associates¹⁵¹ reported an analysis of 129 cases of acute epiglottitis in adults in which no deaths occurred in the cohort, and 85% of these patients were managed without airway intervention.

In the large series reported by Berger and colleagues³⁴ involving 118 cases, 19 had airways established on admission (16 endotracheal intubation, 2 tracheotomy, 1 cricothyrotomy), and 6 other patients subsequently required either endotracheal intubation or tracheotomy. The remaining 93 patients were managed successfully without the need for airway intervention. Fifty-eight of the patients were treated with intravenous corticosteroids in addition to antibiotics, and these patients tended to have more prolonged hospital stays than those who did not receive steroids (5.7 ± 4.1 days vs. 4.7 ± 4.3 days; *P* = .2).

To aid in intubation and reduce long-term sequelae, most investigators have advocated use of a nasotracheal tube 0.5 to 1.0 mm smaller than that predicted by the patient's age.^{192,304,384} Published criteria for extubation¹⁴ include those based on duration of therapy and those based on daily examination of the epiglottis and supraglottic structures by direct laryngoscopy¹⁰⁷ or fiberoptic bronchoscopy.^{329,452}

*References 26, 90, 192, 261, 290, 333, 352, 384, 386, 397, 435, 439.

Long-term complications of nasotracheal intubation are rare. Thirty-three children with epiglottitis who were managed with nasotracheal intubation (mean duration of intubation, 55 hours) were evaluated 1 to 8 years later. By history and measurement of peak expiratory flow rates, no complications were found.³⁸⁴ Although additional long-term data are necessary to ensure absence of residua, elective nasotracheal intubation appears to be the procedure of choice.

Several reports documented the recognition of idiopathic pulmonary edema before²⁷⁰ or, more commonly, after^{3,105,120,148,223,386,416} insertion of an endotracheal tube to relieve laryngeal obstruction caused by epiglottitis. One hypothesis to explain this phenomenon is that airway obstruction produces markedly negative intrapleural pressure with increased venous return to the right side of the heart, with decreased left ventricular output and increased pulmonary blood volume.²⁶⁶ These changes increase the pulmonary microvascular pressure and produce pulmonary hyperemia and edema. Endotoxemia may play a role in altering vascular permeability, but it is not necessary for recognition of this complication of airway obstruction because abrupt onset of pulmonary edema was described when airway obstruction caused by croup, foreign body, and malignant neoplasm was relieved acutely.⁶³ The frequency of pulmonary edema as a complication of intubation in supraglottitis was approximately 9%,⁴⁰⁸ and it has occurred in an adult.³⁶³ Continuous positive airway pressure in all intubated patients with epiglottitis probably will provide prophylaxis against this complication,^{119,154} but controlled data are lacking.

Antibiotics

The mainstay of antibiotic therapy for acute epiglottitis in the recent past has been ceftriaxone 50 to 100 mg/kg per day given every 12 hours intravenously or cefotaxime 100 to 200 mg/kg per day given every 6 hours intravenously because virtually all cases in both children and adults were caused by *H. influenzae* type B. However, in the present conjugate vaccine era, the incidence of all invasive *H. influenzae* type B disease has decreased dramatically. Therefore, in children previously vaccinated, the cause is likely to be another organism. Culture results today have added significance because one possible cause that would require a change in therapy is *S. aureus*.

No controlled data exist about the duration of antimicrobial administration, but a course of 7 to 10 days seems appropriate. In the event that group A streptococci are isolated from the airway, penicillin is the drug of choice. A first-generation semisynthetic penicillinase-resistant penicillin or vancomycin (if MRSA is suspected) should be used for *S. aureus*.

Other Supportive Measures

Expert respiratory nursing care is essential. Inadvertent extubation must be avoided, particularly in the first 24 hours. Judicious use of sedatives that do not appreciably depress respiration may be appropriate.

PROGNOSIS

The prognosis of acute laryngotracheitis has improved markedly during the past 55 years. Today a child with croup only rarely requires a mechanical airway, and virtually all deaths should be preventable. The child should be observed for the following complications: hypoxemia and cardiorespiratory failure, pulmonary edema, pneumothorax and pneumomediastinum, mechanical problems caused by tracheotomies and nasotracheal tubes, and secondary bacterial infections. Children with a history of croup have a higher prevalence of increased bronchial reactivity than children without such history.^{182,284,468}

The prognosis in epiglottitis after the successful establishment of an airway and the administration of specific antimicrobial agents is generally good.

Extraepiglottic complications are not common occurrences in children with acute epiglottitis. In a study involving 72 children with epiglottitis, investigators noted that 25% had pneumonia, 25% had cervical adenitis, 8% had tonsillitis, and 5% had otitis media.³⁰⁹ The other common invasive manifestations of *H. influenzae* type B infections (meningitis, arthritis, and cellulitis) rarely are found in conjunction with epiglottitis.^{309,383}

PREVENTION OF CROUP

At present, acute laryngotracheitis is not preventable. The widespread use of influenza vaccines could reduce the incidence of croup caused by influenza A and B viruses.

Prevention of Epiglottitis Caused by *Haemophilus influenzae* Type B

The universal use of *H. influenzae* type B vaccine in infancy with an additional dose in the second year of life has had a profound effect on the occurrence of invasive *H. influenzae* type B diseases.

In the pre-conjugate vaccine era, household contacts of patients with *H. influenzae* type B infection were at increased risk for acquiring the infection.¹⁷³ Whether an increased risk occurred in daycare contacts was unresolved.¹⁰⁵ Although contacts of patients with *H. influenzae* type B epiglottitis younger than 5 years of age are colonized less frequently than contacts of patients with other *H. influenzae* type B invasive infections,¹⁰⁴ secondary disease was described in household contacts when an index patient had epiglottitis.^{3,169,170,441} Secondary *H. influenzae* type B epiglottitis was described in a child³ and two adults who were household contacts of a patient with *H. influenzae* type B meningitis.^{169,170} *H. influenzae* type B epiglottitis occurred in two siblings who presented with the condition within 1 day.¹⁸⁶

Rifampin prophylaxis with 20 mg/kg per day (600 mg/dose maximum) for 4 days is recommended for all unvaccinated members of a patient's contact group when the index patient has *H. influenzae* type B epiglottitis and at least one contact in the group is 4 years of age or younger.^{9,69}

The recognition that adults occasionally may acquire secondary infection, particularly epiglottitis, on exposure to children with invasive *H. influenzae* type B infection prompted some experts to extend prophylaxis to all of a patient's contact groups regardless of the presence of one or more contacts who are 4 years of age or younger. All experts, however, recommended that adults and older children be made aware of the signs and symptoms of *H. influenzae* type B disease, particularly when the patient's contact group would not receive prophylaxis under current guidelines.
